PREFACE

The participation this conference was significantly reduced by concerns with the US budget process. We are convinced that this is a one time event and we will be back on track next year.
This year we made a major change in the processing of the papers. We required the authors to send us a full paper for review and possible revisions. This change occurred as a result of recommendations of a special quality improvement subcommittee of the Program Advisory Committee. The process worked better than we expected and we will retain the process for WM'97. Please advise us of your opinions and whether we are gaining improvements in the writing of the papers.
We are moving rapidly to utilize the Internet and will shortly have our own web server. We are applying for the name WMSYM.org and will make an announcement on http://basix.com/~wmsym/ when this occurs. We have the Call for Papers on net for free access and will have next years' proceedings on with authorization to each attendee qualifying for a CD ROM version. We will put the preliminary program for WM'97 on and you will be able to register on the Internet. Note that payment by VISA, Master Card or Discover Card will still require a phone call, fax or letter.

Session 01 -- PLENARY
Co-chairs: John D. Hurley, WSRC
Robert G. Holmes, British Nuclear Fuels
1-2
HIGH NOON FOR NUCLEAR POWER
James L. Gallagher
Westinghouse Government and Environmental Services Company
Executive Vice President
ABSTRACT
Spent nuclear fuel management is mired in delay, missed milestones and litigation. Unless the commercial nuclear industry and the government can break the log jam, Mr. Gallagher, believes, nuclear power plants will become too expensive to operate. He draws parallels between the spent fuel debate and "High Noon," the classic 1952 Western. In the movie, Gary Cooper plays a marshall struggling to persuade the citizens of a small Texas town to unite and save the community from a gang of outlaws. To save nuclear energy, the commercial and government sides must similarly unite to resolve spent nuclear fuel problems. Mr. Gallagher believes utilities and the DOE must take three steps to ensure nuclear power's continued viability. First, they must reestablish open, two-way dialogue. Second, they must find common ground on spent fuel issues. Finally, they

must reach consensus on a standard spent fuel canister system to foster a cost-effective spent fuel management solution. He discusses the Multi-Purpose Canister (MPC) and how it can resolve spent fuel issues. One way to break the current deadlock is to go forward with the transportation portion of the MPC system. This action, Mr. Gallagher believes, would move the industry toward a standard canister design without impinging on competition. In a time of budgetary restraint, a limited MPC program could be completed with very little funding, Mr. Gallagher asserts. Equally important, it would allow the industry to begin resolution of potentially sensitive spent fuel transportation issues.

REMARKS

Good morning.

I'm here to discuss spent nuclear fuel management.

I know. It's a touchy subject. . . the cause of debate, discord and division.

I'm not here to continue that debate. I'm here to end it.

Because whenever I hear endless arguments over spent nuclear fuel, I hear the clock ticking. . .

. . .ticking toward nuclear energy's high noon. Make no mistake. Nuclear power's high noon is near. And unless we can find ways to work together, America's nuclear power plants will shut down.

We can't let that happen. Time is running out. It's almost High Noon.

High Noon. . . that classic 1952 western starring Gary Cooper. He plays Will Kane, the courageous Marshall of Hadleyville, a small, dusty town somewhere in Texas. Kane must save Hadleyville from a group of desperadoes. Their leader, Frank Miller, is arriving on the noon train. And when he does, they aim to kill Kane and loot the town.

Fig. 1

Kane must convince the people of Hadleyville to band together. . .face the gang. . .and save the town. He constantly checks the time, ever mindful of the impending disaster at high noon.

The outlaws are armed and ready, impatiently waiting at the station. The High Noon train will bring their leader, and they'll bring destruction to Hadleyville.

While the outlaws prepare for their assault, the good people of Hadleyville argue. They argue over who's responsible for the trouble. And they argue over who should end it.

Sound familiar? Let's drop in on their debate. . .

Citizen #1: "Yes, we all know who Miller is, but we put him away once. And who saved him from hanging? The politicians up north! . . . "

Do you see the parallels between the citizens' struggle and our own? They want to blame the government. They think the government caused the problem, and the government ought to solve it. That's pretty close to the argument of some nuclear utilities in the spent fuel debate.

Here's another point of view. . .

Citizen #2: "Well, I say this. We been payin' good money right along for a Marshall and deputies. Now the first time there's any trouble, we're supposed to take care of it ourselves. Well, what we been payin' for all this time? I say we're not peace officers. This ain't our job. . . ."

That sounds mighty similar to payin' good money into the Nuclear Waste Trust Fund. Utilities, or more correctly, utility ratepayers, have been paying into the fund since it was established by the Nuclear Waste Policy Act of 1982. The fund pays for the government to take spent fuel off the utilities' property beginning in 1998. It also pays for the government to

permanently dispose of the fuel in a federal geologic repository - presumably at Yucca Mountain.

Yet DOE has fallen victim to declining budgets. The opening of the repository has been delayed, initially from 1998 to 2003. . . and, then again. . .to 2010. As the delays appeared, DOE's commitment to accept spent fuel in 1998 began to slip. Its once firm commitment has become a firm "maybe."

The utilities feel betrayed. And DOE is sympathetic. But current law prevents DOE from moving ahead on a specific interim storage site. And the law does not allow DOE to accept spent fuel at any site other than the repository. . .

Citizen #3: "I can't believe I've heard some of the things that have been said here. Y'all oughta be ashamed of yourselves! Sure, we paid this man, and he was the best Marshall this town ever had. It ain't his trouble, it's ours. I tell you, if we don't do what's right, we're gonna have plenty more trouble. . ."

DOE argues there will be plenty more trouble if it moves too quickly on interim storage. That could foster public opposition. And that opposition could sink Yucca Mountain.

Citizen #4: "I've been saying right along we need more deputies. . ."

And I think everyone, except the politicians up North in Congress, has said that we need to devote more resources to the spent nuclear fuel program. After all, the money is there. Twelve billion dollars has been paid into the Waste Trust Fund. But because of Congressional constraints on funding, the DOE doesn't have the authority or the money to fund interim storage or to continue the Multi-Purpose Canister.

And it's concerned that every dollar invested in these programs will divert scarce resources away from Yucca Mountain site characterization, the ultimate goal of the program. . . .

I understand these arguments. They make sense. They're all valid viewpoints in the debate. Unfortunately, the citizens of Hadleyville never understood that words are a poor substitute for action.

While the citizens argued, the outlaws loaded their weapons and got ready to destroy Hadleyville. Their debate and delay gave the outlaws the opening they needed.

We have to understand that our infighting and indecision give ammunition to the anti-nuclear gunslingers. Our arguments give the obstructionists weapons that they will surely use against us. Our division emboldens them. Our court cases provide a public forum to promote their agenda.

The spent fuel issue can shut down nuclear power.

As we continue to argue, time is running out for nuclear power as a viable energy option.

We can't let this happen.

To save the nuclear energy option, we must resolve our differences and move forward, together, to solve the spent fuel problem. Once and for all. And we must do it now.

Let me suggest three steps we can take. Today.

First, we must reestablish open communications between the utilities and the DOE on spent fuel management.

Until last year, communications were good. But that was before Yucca Mountain was delayed and MPC funding was cut. Somehow, the lines of communication seem to have been cut along with the budgets.

This is the heart of our spent fuel management difficulties. It's the reason we're fighting among ourselves instead of solving spent fuel problems.

We need to revitalize communication. Right now. Today. Tom Grumbly was absolutely right when he told The Washington Post. . .and I quote. . . "The only way we're going to get the public's trust is to put our cards on the table. Face up. All the time. Even if it's painful."

We have to maintain full, open and honest communications among ourselves, and with all our stakeholders.

Next, we should recognize the many areas where we already agree. This will reinforce our common purpose. And it will foster mutual understanding, so we can work productively to resolve our points of disagreement.

I think we can all agree that we should take care of our spent fuel problems now. . . instead of leaving them for our grandchildren to inherit.

Another area of agreement. We all recognize the need for a central, permanent spent fuel repository. And until we get one, we need a rational way of storing spent fuel in the interim.

And there's a final point we can all agree on. We need a spent fuel storage system that's safe and cost-effective. Because no matter whose budget the money goes through, it all comes from the same place. Our pockets. As ratepayers and taxpayers, we pay all the bills.

Finally, we must reach consensus on a standard spent fuel canister system. This should be an industry standard. DOE should own the design, so that we get the benefits of competition and private sector manufacturing.

This is an urgent issue.

Seventeen plants already have spent fuel storage systems in place or on order. Twelve more will need storage by the year 2000, and 70 plants will need it by 2010.

In the absence of a standard system, a variety of different canisters are being used. There are single-purpose, storage-only systems. There are dual purpose systems - for storage and transportation. There are metallic casks and concrete casks. There are large ones, small ones, short ones, tall ones. There's everything except your choice of colors. But wait for next year's models.

Variety is great for the family car, but not for safe, cost-effective spent fuel storage.

The DOE is worried about this proliferation of canisters. They have to figure out how to get the fuel out of all those different canisters and into one permanent repository. At a recent NRC hearing, Dan Dreyfus told the commission that a situation could arise "where dry storage (built by utilities) could be so site-specific that it could create a management problem."

The NRC is also worried. At that same hearing, NRC Chairman Shirley Jackson and Commissioner Rodgers expressed concerns about whether different transportation and storage canisters developed by private industry would comply with repository requirements.

And we should be worried.

Because we, as ratepayers and taxpayers are going to have to foot the bill to close the cycle on many of these half-way solutions.

That's why we need a standard solution. We need a solution that accommodates fuel from all of our nuclear plants. We need a solution that

integrates all the elements of the spent fuel program: Storage. Transportation. And permanent repository emplacement.
The solution exists.
It's the Multi-Purpose Canister.
I say this, of course, as head of the Westinghouse unit given responsibility for developing the MPC by DOE's M&O contractor for the high-level waste program.
But I also say it as a 30-year veteran of the nuclear field, and as a person who cares deeply about keeping the nuclear option open.
A significant benefit of the Multi-Purpose Canister is its ability to accommodate 90 percent of the utility spent fuel inventory. Today's storage and transportation canisters can accommodate only a fraction of that fuel.
Fig. 2
In addition, today's canisters won't be accepted at the repository. Once fuel is loaded into the MPC, it stays in the MPC - through storage, transport, and into the repository.
Radiation exposure is minimized, and so is low-level waste. Other canisters must eventually be scrapped as their fuel is transferred to the repository. That will create huge amounts of low-level waste. And huge costs. Because we'll have to pay to re-handle the fuel; we'll have to pay to dispose of the scrap canisters, and we'll have to pay for new repository canisters.
Fig. 3
So without the MPC, we'll pay more for spent fuel management. A lot more. That's what the obstructionists want. They'd like us to price nuclear power out of business.
We can't let that happen.
And we don't have to. This spring, the MPC design will be complete. Let's take a look at it.
Fig. 4
The Multi-Purpose Canister system includes:

- The canister with its basket assembly
- A transfer cask to move the fuel to on-site storage
- A concrete storage unit, and
- A transportation cask and rail car to transport the MPC off site.

Here's how its used. In the fuel pool, each spent nuclear fuel assembly fits into a guide tube constructed of 304 stainless steel. Spacer plates secure the guide tubes. The spacer plates are assembled with support rods and sleeves to form the basket, which ensures that the fuel remains subcritical. The MPC basket is constructed of XM-19, the same corrosion resistant stainless steel used in sulfuric acid processing plants.
The MPC shell is 316L stainless steel. A shield plug uses depleted uranium in a stainless steel shell to attenuate gamma radiation. A 1-1/4 inch thick 316L stainless steel inner closure plate forms the primary containment boundary, and a 1-3/4 inch 316L stainless steel outer closure plate provides a redundant seal.
During loading, the MPC canister is enclosed in a reusable transfer cask that provides neutron and gamma shielding, heat dissipation, and structural protection. The MPC can then be transferred to a concrete storage unit for on-site vertical storage, or it can be transferred to a reusable transportation cask for shipment off site.
The transportation cask consists of four layers: The inner shell is XM-19, surrounded by a layer of depleted uranium which provides radiation

shielding. This feature also provides a margin of strength and toughness in physical testing, which would not be present in an equivalent lead-steel or all-steel design. The third layer is an XM-19 structural shell. The fourth layer consists of neutron shielding and copper fins. Proven, cast-in-place cementious material is used to attenuate neutron radiation through the cask wall. Boron, added to this neutron shielding material, reduces secondary gamma radiation from neutron absorption. Effective shielding is balanced with heat transfer requirements through the use of copper ribs, which dramatically improve the flow of heat to the outside of the cask. A thin copper-lined stainless steel jacket encloses the cask.

For transportation off-site, the trunnions are removed and the cask is fitted with large polyurethane foam and honeycomb aluminum impact limiters and the personnel barrier. In this integrated system, the storage, transfer and transportation casks are reusable.

We need the MPC. We need to get this standard spent fuel solution out of the computer and into the nuclear power plants where it's needed.

Let me suggest a path forward.

The most expedient, cost-effective way to do this is for DOE to allow the transportation portion of the MPC program to go forward.

Let me explain the benefits.

First, it will move the industry toward a standard solution without infringing on competition.

Second, it will maintain the momentum of the MPC program, making a standard spent fuel storage system available as soon as possible for the utilities that need it.

Third, it will only cost about $10 million to license the MPC transportation components. That's about one percent of the projected Yucca Mountain expenditures through 2010. I think that's a small price to pay to help move the industry confidently ahead on spent fuel storage. In this time of budgetary restraint, it's the right thing to do.

Finally, a government-certified standard transportation cask will take an important weapon away from the obstructionists. Transportation has the potential to be one of the most contentious spent fuel management issues. People worry about nuclear waste moving through their communities, even though our transportation safety record is perfect.

That's why DOE and Westinghouse tackled transportation issues early for the Waste Isolation Pilot Plant, near Carlsbad, New Mexico. Well before the repository was ready to open, the TRUPACT II transportation casks were designed, tested and certified. The transportation routes were established, and emergency response personnel were trained. So transportation is not an issue as the repository clears its final regulatory hurdles on the way to a 1998 opening.

By moving forward with the transportation portion of the MPC, we can resolve one of the most contentious issues in spent fuel management.

The obstructionists, like the outlaws in High Noon, would like to use transportation and other spent fuel issues to hold nuclear power hostage. And we are giving them the opportunity. Because we are allowing debate and division to keep us from taking the responsible actions needed to solve these issues.

I believe we can learn a lot from this Hadleyville citizen...

Citizen #4: ". . .so if Miller comes back here today, it's our problem. It's our problem, because it's our town. We made it with our own hands out of nothing. And if we want to keep it decent, keep in growing, we've

got to think mighty clear here today. And we've got to have the courage to do what we think is right, no matter how hard it is. Alright."
We have to do what's right, no matter how hard it is. And we have to do it now. Time is running out. High Noon is nearly upon us.
In the movie, the townspeople never did stop arguing long enough to band together and back Marshall Kane. He had to face the gunmen alone. And yet he still saved the town. . . and got the girl.
But that's Hollywood, my friends. This . . . is the real world.
America's great accomplishments don't come through the courts. They come through cooperation, communication, and responsible action. They come by working together to solve tough problems.
Nuclear power can keep our country strong and secure. Our story can have a happy ending, too, but only if we keep the spent fuel issue from taking us hostage.
We must put our differences behind us. We must all become deputies in the struggle to save nuclear power. Today.
Right now, we can end our unproductive arguing, eliminate our excuses and move forward on a standardized spent fuel storage system.
Let's all become spent fuel action deputies. Let's saddle up together to put our spent fuel problems behind us. And let's move now. While there's still time.
Let's ride!

1-3
THE GLOBAL IMPLICATIONS OF OPENING THE WASTE ISOLATION PILOT PLANT

George E. Dials
U.S. Department of Energy
Carlsbad Area Office
Carlsbad, NM USA

ABSTRACT
A missing global link in the nuclear fuel cycle and safe radioactive waste management is the opening of the world's first permanent facility for the safe disposal of long-lived radioactive waste such as transuranic radioactive waste (TRUW), and spent nuclear fuel and other high-level radioactive wastes (HLW). Pursuant to current laws in the United States, both TRUW and HLW will be disposed of in deep geologic repositories, but at different locations. This paper provides our estimate of the situation and the global impact of opening a TRUW repository at the Waste Isolation Pilot Plant (WIPP) site in the state of New Mexico.
The WIPP project began in 1974 and it has a long-standing record of excellent science and safety. In October 1993, the United States Department of Energy established the Carlsbad Area Office (CAO) with a mission to review and integrate the safe management of all TRUW in the USA. By April 1994, the CAO had conducted the review and implemented a new mission which included an accelerated schedule for the opening of the WIPP in 1998 rather than in 2001. Subsequently, the CAO has set precedents at the WIPP with early regulator and stakeholder involvements in the regulatory process, and with the development of a detailed, well-structured, and defensible decision-making basis for the most cost-effective path to the timely opening of the WIPP in 1998.
At the end of August 1995, the WIPP is well into the certification/permitting process and on schedule to open in 1998. The timely opening of the WIPP repository would reduce risks and increase the protection of human health and the environment by removing existing TRUW

from surface-based and near-surface-based temporary storage facilities to a repository located at a depth of approximately 650 meters below the land surface. Moreover, the opening of the WIPP repository would be a global first-of-a-kind operational facility, and its continued safe operation in compliance with one of the strictest environmental radiation protection standards in the world should enhance public confidence in the safety of deep geological disposal of TRUW and HLW both in the USA and abroad.

INTRODUCTION

A missing global link in the nuclear fuel cycle and safe radioactive waste management is the opening of the world's first permanent facility for the safe disposal of long-lived radioactive waste such as transuranic radioactive waste (TRUW), and spent nuclear fuel and other high-level radioactive wastes (HLW). Pursuant to current laws in theUnited States, both TRUW and HLW will be disposed of in deep geologic repositories, but at different locations. This presentation provides our estimate of the situation and the global impact of opening a TRUW repository at the Waste Isolation Pilot Plant (WIPP) site in the state of New Mexico.

THE SITUATION

The WIPP site was selected in 1974 as a potential site for the development of a facility for disposal of defense-related TRUW generated since the 1970 decision by the Atomic Energy Commission (a predecessor agency to the DOE) to begin above ground interim storage of transuranic waste rather than shallow burial. In 1992, the WIPP site was withdrawn from public use by the US Congress for completion of the development of the nation's TRUW repository.

The DOE established the Carlsbad Area Office (CAO) in December 1993 to:

1. Integrate the characterization and preparation/packaging of existing and future TRUW at ten main TRUW generator/storage sites through the National TRU Program (NTP); and to
2. Open and operate the nation's first deep geologic disposal system (repository) (Fig. 1) for TRUW at the WIPP site.

Fig. 1

THE PROBLEM

It is estimated that 144,000 cubic meters of TRUW exists in the U.S. Approximately 63,000 cubic meters is already packaged. It is contained in a variety of metal drums and wooden and metal boxes. Since 1970, the waste has been placed in retrievable storage. They are stored in earth-covered mounds, concrete culverts, and other types of facilities. Over 70% of the drums are over 10 years old and 20-30% of the drums stored in mounds contain corrosion pinholes or are beginning to deteriorate. This waste is dispersed across the country with five major sites containing 96% of the waste. Remediation and decommissioning of facilities are expected to package another 81,000 cubic meters of TRUW. Over 30 million people live within a 50 mile radius of TRUW. Taxpayers are supporting a budget that spends approximately $400 million a year to maintain this waste in temporary storage.

THE SOLUTION

As early as 1957, a National Academy of Sciences (NAS) report to the Atomic Energy Commission recommended the burial of transuranic waste in geological formations. A 1992 report from the NAS notes that most countries have concluded that "the best means of long-term disposal...is deep geological emplacement...."

The WIPP site was identified in 1974 as a potentially suitable site for a TRUW repository, and an extensive site characterization program was initiated. The 6.4 by 6.4 Kilometer (Km) WIPP Site is situated 42 Km Southeast of Carlsbad, New Mexico in an arid and sparsely populated desert area. Based on the results from the site characterization program (including laboratory testing, model developments, and analyses), the construction of an underground test facility at an approximate depth of 650 meters below the surface in the center of the candidate host rock, the Salado Formation, commenced in 1982. The Salado Formation is about 250-million-years-old, regionally extensive, 600-meter-thick, stable, sedimentary evaporitic sequence of rocks dominated by rock salt (mainly halite). The construction and testing of the underground facility as well as all facilities and equipment required to commence the receipt, handling, transporting, and emplacement of TRUW were essentially completed in 1988.

THE APPROACH

Since the inception of the CAO, a preliminary waste inventory has been compiled, the experimental program has been streamlined, three permit/certification applications have been submitted to the regulators, the schedule for opening the WIPP repository has been advanced almost three years to April 1998, and the estimated cost to open the WIPP repository has been reduced by more than 300,000,000 dollars.

The NTP has periodically inventoried and updated available information on TRUW at some 20 generator/storage sites and projected future TRUW generation. The most current estimated stockpile of TRUW is about 59,000 m3 of Contact Handled-TRUW and 4,000 m3 of Remote Handled-TRUW.

During 1994 and 1995, the CAO evaluated the experimental programs in terms of contributions to regulatory compliance by means of the System Prioritization Method (SPM) to establish the most promising combination(s) of activities to meet the final disposal standards for TRUW, i.e., Code of Federal Regulations, Title 40, Part 191 (40 CFR 191). Based on the SPM results, the Manager of CAO decided in April 1995 to reduce the experimental programs from 116 activities to eight activity sets. The SPM initiative also pioneered early and iterative regulator and stakeholder involvement in the process of regulatory compliance.

After a thorough evaluation of the WIPP experimental programs, the TRUW inventory (both existing and projected), and the engineered barriers, the Carlsbad Area Office announced a new TRUW management strategy on April 5, 1994. This strategy accelerates the opening of the WIPP repository by three years, i.e., from 2001 to 1998, and the key milestones are shown on Fig. 2, the WIPP Disposal Decision Plan. The main objectives of this strategy are to:

- resolve regulatory compliance and technical issues;
- characterize the waste;
- address transportation and safety issues; and
- involve stakeholders in the regulatory compliance process.

Fig. 2

In 1995, the WIPP entered the permitting phase. The following three applications to receive and dispose of TRUW and mixed-TRUW at the WIPP site were submitted to the cognizant regulator:

1. The Draft Compliance Certification Application (DCCA), describing how TRUW will be safely received and disposed at the WIPP site, was submitted to the Environmental Protection Agency (EPA) on March 31, 1995;

2. The draft No-Migration Variance Petition (NMVP), demonstrating that hazardous constituents will not migrate from the WIPP repository at concentrations harmful to human health and the environment for 10,000 years, was submitted to the EPA on May 31, 1995; and

3. The Resource Conservation and Recovery Act (RCRA) Part B Permit, describing the site, its facilities, and how the hazardous waste received at the WIPP site will be safely handled on a daily basis, was submitted to the New Mexico Environment Department on May 31,1995, one month ahead of the Disposal Decision Plan schedule.

Regulator comments on these applications were received by the CAO during 1995. Additional regulator, oversight groups, and stakeholder comments are expected in 1996. These comments will be considered and responded to prior to the submittal of the Final Compliance Certification Application to the EPA in October 1996.

TRANSPORTATION/SAFETY ISSUES

Since the beginning of this country's nuclear program, there have been more than 2,500 shipments of spent fuel and many more shipments of low-level waste. The safety record to date is very good. Transportation of nuclear waste is of particular concern to states and Native American tribes along the main transportation routes to WIPP. DOE, state and tribal governments, and several national and regional transportation organizations are actively preparing for potential shipments of transuranic waste to the facility. These preparations include the development of policy and procedures for preventing accidents, responding to emergencies and bad road and weather conditions, conducting inspections, and providing equipment.

Packaging provides the primary barrier to the release of radioactive contents during shipment. The Transuranic Package Transporter (TRUPACT II) containers have been especially designed to ship waste to the WIPP. This system meets or exceeds every Department of Transportation and Nuclear Regulatory Commission regulation and is the safest method ever devised for transporting any hazardous material in the US.

IMPEDIMENTS

The CAO works with 16 federal agencies, 23 states, and 39 Indian Tribes. The CAO is committed to increased interaction with all stakeholders regarding major decisions. The CAO is involving stakeholders throughout its decision making process in a visible and accessible way, from start to finish. That is, stakeholders are advised early of involvement opportunities, comments will be encouraged, and stakeholders will be provided with responses and program updates. Our aim is to surface and resolve concerns before they become more difficult and costly to resolve. Trying to satisfy all these customers is about as easy as "herding cats" or actually "herding turtles" in the often-bureaucratic arena in which we work. Besides trying to align all these disparate political agendas, we have to overcome all the misconceptions held by stakeholders. For example, some people along the transportation corridor fear that they will suffer harmful radiation effects during the shipments, a fear fed by the often over-stated, emotional attacks by those special interests opposed to nuclear activities and supported by non-factual statements about the hazards or risks from low-level radiation exposure.

In the regulatory arena, which will be covered in greater detail tomorrow at Session 19, we are required to predict the performance of the repository for 10,000 years into the future. That is two times the age of the pyramids. Given this extraordinarily difficult task, we are applying

the most sophisticated state-of-the-art performance assessment analyses process currently in use; we will try and predict the natural resources needed thousands of years into the future, predict natural forces and changes in the earth, and then defend the soundness of the WIPP repository to the EPA, New Mexico Environmental Department, and other stakeholders. Compared with these requirements, performing on schedule, with a shrinking budget, is easy.

IMPACT

The opening of the WIPP repository will drastically reduce risks to human health and the environment by facilitating the removal of existing TRUW from surface-based and near-surface-based storage facilities and contaminated sites, to a TRUW repository located in a virtually uninhabited desert area at a depth of approximately 650 meters below the surface in the center of a stable and virtually impermeable rock salt formation. Several of the TRUW storage sites are located in the vicinity of sizable population centers. If there is any risks to the public and/or the environment from the alpha radiation emitted by TRUW, it is orders of magnitude greater where the waste is than where we are trying to put it - 650 meters deep in a 250 million year old salt formation.

Moreover, the WIPP will be a world-class first-of-a-kind facility for safe disposal of long-lived TRUW. It will be the first permanent repository licensed under a rigorous, ultra-conservative regulatory program requiring a risk-based performance assessment to demonstrate compliance with the environmental standards for 10,000 years. Its continued safe operation in compliance with several hazardous waste regulations and one of the strictest environmental radiation protection standards in the world will enhance public confidence in the safety of deep geological repositories both in the USA and abroad.

As part of our compliance program efforts, the CAO has requested a review of the WIPP performance assessment effort by the Organization for Economic Cooperation and Development/Nuclear Energy Agency (OECD/NEA) and the International Atomic Energy Agency (IAEA). These two international agencies have had long and effective involvement in the nuclear arena throughout the world. The eminent engineers and scientist on the OECD/NEA and IAEA team who are renowned; world wide budget matter experts, will prepare an independent review of the WIPP's program to demonstrate compliance that will serve as a model for other assessment and licensing efforts. Our approach to engaging the regulator early-on in technical discussions in the licensing process and to including the public in the early stages of the effort will serve as a model that can be replicated in other nations licensing efforts. As we have in the past, we are prepared to share our lessons-learned with the international community through our involvement with the IAEA and/or OECD/NEA or any individual nation-to-nation basis. Many of our foreign colleagues, especially those who attend this meeting, have already toured the WIPP and endured extensive technical and regulatory briefings about our approaches to and the status of the scientific, operational and regulatory aspects of the CAO program for operating the WIPP.

CONCLUSION

Whether or not you live near a nuclear TRUW site, the success of the WIPP will have significant effects on public health and on the economy and environment in which you and future generations will live. Any taxpayer, electricity consumer, environmentalist, public health advocate, or

individual who is interested in solving this national dilemma of waste management, should become a champion for the WIPP.
For those who haven't visited the WIPP yet, I want to end this presentation by issuing you a personal invitation for a VIP-tour of and detailed briefing about WIPP. It will meet your highest, world-class expectations for a nuclear waste repository.

EXPERIMENTAL BOILING WATER REACTOR D&D
ES&H LESSONS LEARNED
W. H. Hannum
A. E. Knox
Argonne National Laboratory
ABSTRACT
The decontamination and decommissioning of the Experimental Boiling Water Reactor (EBWR) was well planned and professionally accomplished by an experienced contractor. In the process, two particular radiological incidents occurred that were outside of the planning envelope. The first involved trace Pu-241 that had decayed to Am-241 and that was vaporized during size reduction. The second involved microspheres of activated steel that were produced in condensation of plasma-arc cutting vapors. While neither resulted in significant exposure, the americium uptake was clearly an "unreviewed safety question," and both deserve attention as lessons learned.
BACKGROUND
The Experimental Boiling Water Reactor (EBWR) was built in 1957 as an experimental facility to demonstrate the practicality (stability, control, etc.) of a boiling water reactor. As with most experimental facilities built in that period, a wide variety of experimental configurations and fuels were used. It is reported that there were no fuel failures during the operation of EBWR. The final configuration included plutonium fueling for the central nine assemblies.
In 1967, the reactor was shut down, defueled, and placed in a "stable interim condition." Little was done at the facility until 1993. In the 1980 time period, the containment structure was used for interim storage of contaminated glove boxes. In 1979, NUS did a survey and preliminary planning for decontamination and decommissioning of the facility. Significantly, NUS surveys concluded that there would be no alpha (fuel) hazard in the D&D of this facility. Further preliminary surveys and planning were done in 1989-1990, confirming (or more literally, repeating) the assessment that there was no alpha hazard. The only identified radiological hazard was from activation products, dominantly cobalt-60. When waste management funding was obtained for D&D of the facility, there was some question as to DOE's requirement for safety analyses for D&D projects and planning proceeded based on best judgement as to the required analyses. A contract was placed with ALARON, who has worked as subcontractor on many nuclear D&D projects but never before as the lead contractor. ALARON was advised that there was no identified or anticipated alpha concern, but the contract terms called for ALARON to do a characterization survey. That survey also confirmed that there was no alpha contamination. Health Physics (HP) coverage was assigned to ALARON

by the contract with oversight by ANL Health Physics. Entrance and exit bioassays for all subcontract radiation workers were also required, with ANL providing the bioassay support (ANL employees are covered by a periodic assay program based on their exposure potential). Respiratory protection was required (and used) by all workers until it was confirmed that there was no significant airborne cobalt-60 contamination.

DOE later ruled that all D&D projects were to be considered "nuclear" projects and subject to the full DOE Order 5480 set of requirements. Based on this, a contract was placed with NES, an experienced group in the preparation of SAR's, to prepare an SAR in accordance with DOE Order 5480.23. The EBWR SAR states that there is no alpha or fission product hazard, and analyzed, as potential accidents, a crane failure dropping heavy contaminated objects and a tornado causing release for contamination. Since the source term is limited, neither of these accidents is found to be a significant public hazard.

THE AMERICIUM INCIDENT

The first phase of the project was the removal of support systems. When the workers who did that work completed their assignments and left the site, they submitted the normal urinalysis samples. When these were analyzed (in August 1994), clearly measurable levels of tritium were noted. As there was no expected tritium (or identified reason to expect tritium), a more thorough analysis was performed (samples were taken in late August and urinalysis samples were analyzed by September 2). The second phase of the D&D was already underway with the size reduction of core internals, vessel and vessel-pit lead removal, and chipping of concrete. The workers involved in these operations were also part of this bioassay review. Among this latter group, measurable alpha uptake was noted in seven urinalyses and confirmed by fecal analysis to be americium-241. Estimates are that the most highly exposed individual could have obtained a lifetime Cumulative Estimated Dose Equivalent (CEDE) of no more than 300 mrem (Table I). Bioassay results are now complete, and seven individuals show alpha levels in their urinalysis, twelve detectable in fecal analysis. Each of these also shows detectable, but not radiologically significant, uptake of tritium, cesium-137, and cobalt-60.

Upon confirmation of biological uptake via analysis of fecal samples (September 9), all work on the project was suspended pending a complete analysis of the situation.

Various ANL "old-timers" suggested a variety of potential sources for the americium, but no specific recollection of a concentrated Am-241 source was identified. The potential sources included fueled control rod followers and intentional failed-fuel experiments. Both fueled followers and failed-fuel experiments were documented in EBWR test reports and were performed well before the plutonium fueled operations. These earlier experiments involved the use of U-235 and U/Th fuel, respectively, and were documented as having been removed from the reactor. Because of the nature of the fuel, it was unlikely that these were sources of the Am-241, although the failed-fuel experiment would have resulted in fission product release to the reactor system. There was no evidence that fueled followers had been used in control rods during the Plutonium Recycle Program. A careful review and analysis of the radioactivity patterns measured from the control rods demonstrated that no fueled followers were involved in the D&D cutting operation.

Table I

Since Am-241 is a daughter of Pu-241, the committee concentrated on the Plutonium Recycle Program activities that were conducted as part of the last experimental program before the facility was shutdown and placed in dry lay-up. A committee member reviewed monthly Reactor Development Progress Reports generated during this time period. These reports highlight the various reactor programs in operation at the time. This review identified references to an experiment for the measurement of epithermal capture-to-fission ratios of Pu-239 and Pu-241 during power operation in EBWR. This experiment involved the placement of Pu-239 and Pu-241 foils in the EBWR reactor core. Further reviews of the Reactor Physics Division annual reports found a notation that one Pu-241 foil was "lost in EBWR" (ANL-7310, page 42). This was confirmed in the experiment final report (ANL-7795). The existence of this "lost" foil was not identified in pre-job characterization.

Although the Pu-241/Am-241 foil has not been found, the air sample and bioassay data appear to be consistent with the estimated Am-241 foil activity level. A "reverse" calculation of the source term from the maximum measured internal dose resulted in an Am-241 source of the same order magnitude of activity as the lost foil.

The sample measurements indicate that the Am-241 activity is located in the fuel pool, and that particular work associated with the fuel pool, such as underwater plasma arc cutting and pool water filter replacement, causes dispersion of airborne Am-241. Since Am-241 was measured in air samples over many different days, it appears that the Am-241 is a diffuse source. If an intact foil had been contacted with the plasma arc, it is likely there would have been a very large release on a particular day, which is not indicated in the air sample data. The foils were produced by vapor deposition onto a Zr carrier, which was then encased but not sealed. It is likely then that the americium, as generated from decay of the Pu-241, would be released as a colloid, depositing out as crud on the reactor internals.

Fig. 1.

Plasma-arc cutting of the internals vaporizes the materials in the cutting path. The underwater plasma arc uses an inert carrier gas, which transports vapors to the surface of the pool as airborne contamination. The original foil contained only about 200 micrograms of plutonium, and only small fractions of this could have been released, but the quantities are not inconsistent with the observed uptakes. Excluding vaporization and a reasonable direct inhalation pathway, the quantities are not significant.

The one parameter that does not fit this hypothesis is the plutonium isotopic mix. If the Pu-241 foil were the sole source, there would be essentially no Pu-239 or Pu-240, whereas the Pu-239 and Pu-241 are about equally present.

A second candidate source is tramp uranium. In the early days of nuclear power, some tramp uranium on the exterior of the fuel pins was considered normal. The system contamination from fuel failures was expected to be large, and small amounts of tramp uranium would be readily accommodated. It is unlikely that the core contained sufficient uranium to account for all of the americium, but it is considered likely that this (or failed-fuel) is responsible for the Cs-137 encountered, and probably accounts for a significant part of the plutonium found in the system. The irradiation products from several tens of grams of uranium, combined with the foil described above, provides a credible source for the observed

radionuclides. This plutonium would be almost totally Pu-239, suggesting broadly comparable contributions from the lost foil and from tramp uranium. The dose, however, is almost totally from Am-241; that is, from the foil.

The possible effect of tramp uranium was not considered in pre-job evaluations.

The assumption that there were no transuranic source terms for the EBWR D&D project resulted in the implementation of an inappropriate radiation monitoring and air sampling program and inappropriate work practices. These practices included discontinuation of respirator use upon confirmation of no significant gamma (Co-60) airborne activity. Thus, for the majority of plasma arc cutting work respiratory protection was not used, nor was there a local capture exhaust around the fuel pool. At the levels identified, radiation detection was not set up with a low enough minimum detection levels to allow detection of alpha radiation that would be of concern. Further, the alpha contamination free release criteria of 20 dpm/100 sq. cm., even though permitted by the DOE Radiological Control Manual, was not sensitive enough to flag that a problem would be created by unprotected plasma arc cutting.

Smears of the EBWR shell area by ESH-HP following the project shutdown did find alpha contamination but at levels far below free release criteria. This fact is probably attributable to the low levels of alpha contamination that were generated along with the regular general housekeeping that was required to remove beta/gamma contamination as well as that required to clean up dust that infiltrated the shell from outside.

Tritium Sources

There are a variety of methods by which tritium could have been generated during EBWR operation including activation of naturally occurring deuterium, as a product of fission and as a product of the use of boron for reactivity control. The latter reaction occurs for high energy neutrons (> 1 Mev). In commercial reactors, tritium production is approximately two orders of magnitude higher in PWRs than in BWRs because of the use of soluble boron for reactivity control in PWRs, based on published liquid effluent data. In contrast to current BWRs, boric acid was used to reactivity control in EBWR. There were also a variety of other components that contained boron, including control rods and the thermal shield. There is no evident conclusion as to what the specific source is or why the tritium (tritiated water) would be found primarily in the fuel pool. Although the tritium levels are a minor dose concern, the production of tritium during operation would have occurred, and residual amounts should have been expected.

Lessons Learned: Americium Incident

1. Reactor internals, piping, and components must be assumed to be generally contaminated with very small amounts of uranium, plutonium fission products, and tritium, in addition to cobalt-60 and secondary activation products.
2. The source of these contaminants includes:
 a) Tramp uranium and incidental fuel failures that undoubtably occur during operation of all but the most modern reactors
 b) Tritium from boron control rods and soluble boron when used.
3. The levels of contamination may be below the threshold for identification by many traditional survey techniques and still constitute a hazard to D&D workers.

4. Plasma-arc cutting has become a common tool for D&D. Cutting contaminated materials will necessarily produce airborne contamination. This project did not adequately assess plasma-arc cutting as generating a radiological inhalation hazard.
5. A generally knowledgeable and cautious overall approach to worker health and safety, plus some degree of redundancy in levels of protection, is required to provide an adequate margin of safety.

Conclusions - Americium Incident

1. In old light water cooled reactors (LWRs), the reactor internals, piping and components are likely to be generally contaminated with small amounts of americium, plutonium, fission products and tritium, in addition to the cobalt-60 and secondary activation products that had been analyzed in the SAR as potential radiological hazards.
 a) The levels may be below the threshold for identification by many traditional survey techniques.
 b) The contamination may well qualify as "fixed," but high temperature techniques such as plasma arc cutting can serve to release "fixed" contamination.
2. The sources of all contaminants are unlikely to be conclusively identifiable.
 a) The source of the fission products can be reasonably associated with tramp uranium and incidental fuel failures that undoubtably occurred during EBWR operation. These sources are likely to be present in all old reactors.
 b) No specific source of the tritium has been identified. Since this does not appear to be a significant radiological hazard for this project, no further effort was made to identify the origin. The presence of tritium is likely to be a property of any old (or new) reactor.
3. Prior evaluations and assessments must not be accepted without adequate questioning. Evidence of inadequate documentation to support the working conclusions should be taken as a clear basis for suspicion. In the EBWR case, there were repeated assurances that the only radiological hazard was from activation products (dominated by cobalt-60). Several surveys had been used to confirm this premise. The contract was written, and the contractor was led to believe that protection against cobalt-60 was all that was required.
4. Hazards associated with specific D&D techniques (e.g., plasma arc cutting) must be explicitly included in safety analyses and in work planning.
5. Literal compliance with all applicable DOE orders and an exhaustive safety analysis performed in accordance with best current practices are no protection against surprises of this sort. The potential radiological hazards associated with "other contaminants" such as americium, plutonium, tritium, and fission products are not likely to be identified during the even very careful project planning. Therefore, both surveillance planning and surveillance execution must plan for surprises.
6. The bioassay program should be designed to confirm that no significant exposure occurred during the project as evidenced by not only a pre-project and post-project sampling regime but by appropriate periodic sampling. The role of the bioassay program in identifying an otherwise unanticipated hazard should be considered solely for confirmation, not detection.
7. Given that a major concern in D&D must be the protection of workers when they encounter unanticipated sources of radionuclides, and given

that excessive protective gear is highly counterproductive, it is clear that an extensive retrospective sampling and assay program covering all credible contaminants and all potentially exposed individuals is essential. Confirmation of negative findings should be built into planning as scheduled hold points commensurate with a credible risk exposure.

8. A generally knowledgeable and cautious overall approach to worker health and safety, plus some degree of redundancy in levels of protection, can provide the margin of safety.

THE MICROSPHERE INCIDENT

In an unrelated incident, Health Physics surveys discovered contamination in a small pile of floor sweepings. The ANL Health Physics technician on duty was conducting "direct surveys" and discovered contamination with an approximate activity level of 107,000 dpm Beta-Gamma in a small pile of floor sweepings that were within the controlled area of the shell but not an area designated as a contaminated area. At that time, additional direct surveys in the same general area found an ambiguous but high reading of fixed contamination on a small spot under a plate. Direct surveys were continued due to the fact that routinely conducted smear surveys of the area had failed to turn up this contamination.

This contamination has been determined to be small pieces of slag produced by plasma arc cutting operations. This material is in the form of very small hollow spheres ranging in size from a quarter inch in diameter to pin-head size. These spheres are not detectable by smears in that the activity of any one or few spheres is below detection limits. The primary radioisotope in the spheres is Co-60 with some Sb-125, indicating activated stainless steel.

Material transfers during the D&D operation are accomplished by establishing a work area; the floor is covered with plastic sheeting and the area is posted. After packaging is completed, the area is wet mapped and smeared for loose contamination. The plastic is then removed and discarded. It is likely that the small spheres were rolled off the plastic by the mopping. Since they are not detectable by smears, some can remain on the floor undetected. The background radiation in this area complicates finding the spheres by routine direct surveys.

In this incident, the pile of floor sweepings had a large enough collection of material in a low background radiation area to allow detection.

The entire area that had been used as a work area was subsequently vacuumed with a HEPA filtered vacuum and sources of background radiation moved to allow for direct survey of all floor surfaces where possible. Vacuuming and using duct tape have been very effective in picking up these slag spheres.

Conclusions and Lessons Learned

In a high background area, there can be significant contamination that is not detected by smear techniques, and other techniques must be used for sampling, detection, and analysis.

Plasma arc cutting is an accepted size reduction technique for many applications, including work on contaminated and activated materials. Detailed procedures must be put in place and implemented for control of contamination resulting from such cutting. It has not been previously recognized that the plasma vapors can result in condensation microspheres that roll freely (including rolling off plastic matting as it is being removed). The microspheres are not effectively collected on swipes, and

microspheres from activated steels may be low enough in activity to be undetectable by normal radiological surveys when dispersed.
Searches for this type of loose contamination in high background areas can be carried out using vacuuming through HEPA filters with subsequent measurement of the filters in a low background area.
This is another in a series of lessons learned from this particular D&D project. While the radiological consequences were minimal and corrective actions readily identifiable, the implications for other D&D work is significant due to the broad application of plasma arc cutting.

FINAL COMMENTS

In both of these instances, plasma arc cutting has produced contamination pathways that were not identified and that were beyond the reasonable range of empirical identification. Given that D&D should be conducted efficiently, modern tools such as plasma arc cutting must be used. As a consequence, such surprises must be expected. To ensure that the risks involved are minimal, defense in depth is essential; rigid formality and procedures are of limited value in that D&D will always have surprises.

2-2

WHO IS LIABLE FOR WORKER HEALTH & SAFETY? LESSONS LEARNED FROM THE MILWAUKEE TUNNEL EXPLOSION: THE ENGINEER'S PERSPECTIVE

David W. Miller
CH2M Hill

ABSTRACT

Determining responsibility for worker health and safety on a construction site is an increasingly difficult task. A methane explosion in Milwaukee in November 1988 killed three employees of the construction contractor. The engineer on the project, CH2M HILL, subsequently became embroiled in five separate legal proceedings arising out of its role on the project, providing services to the owner during construction. Despite express contract language which placed sole responsibility for construction site safety on the contractor, CH2M HILL spent hundreds of thousands of dollars in legal defense costs, including dismissal of OSHA citations by the Administrative Law Judge.
The paper describes the background of the project, and the accident, the resulting legal proceedings, and the lessons CH2M HILL learned from its experiences. Of critical importance, the author emphasizes how different the perspectives are of those involved; the owner, the contractor, the engineer, and the enforcement agencies.

INTRODUCTION

On the early morning of November 10, 1988, an explosion ripped through an underground tunnel being constructed as part of the city of Milwaukee's Water Pollution Abatement Program (the Program). Three employees of the tunneling contractor, S.A. Healy, were killed instantly, and work on the tunnel was postponed for the next several months.
Immediately following the explosion, there were a number of investigations to determine the cause of the explosion and to assess blame for the deaths of the three workers. CH2M HILL, the Program Manager on behalf of the Milwaukee Metropolitan Sewerage District (MMSD), became embroiled in five separate legal proceedings, spending hundreds of thousands of dollars to defend its activitiesdespite express contract language which placed sole responsibility for the health and safety of construction workers on S.A.Healy and its personnel.

The purpose of this paper is to explore lessons learned from the explosion, outlining how health and safety responsibilities were allocated on the Program, and discussing CH2M HILL's approach to health and safety issues, as impacted by the lessons learned.

THE PROGRAM

In the early 1970's, the City of Chicago sued the City of Milwaukee alleging that Milwaukee's sewage was polluting Lake Michigan. As a result of that lawsuit, the City of Milwaukee undertook a massive wastewater improvement program. The Program took 18 years, used 20 million hours of construction work, cost $2.29 billion, and included substantial upgrades at two wastewater treatment plants, the development of an in-line storage interceptor system, and deep tunnels to handle combined overflows from sewage and rain water. Utilizing 324 construction contracts, the MMSD and its Program Manager, CH2M HILL, oversaw total construction costs of $1.6 billion dollars. The Program was completed on time and on budget in the fall of 1995.

A major portion of the Program involved underground construction, including approximately $900 million in construction contracts. The result was over 20 miles of tunnels 300 feet below the ground surface, ranging in diameter from 17 feet to 32 feet; 24 drop shafts and approach channels; and over 62 miles of near surface collector tunnels, ranging from 5 feet to 12 feet in diameter, at a depth of 30 feet to 100 feet below the ground surface.

CH2M HILL managed a consortium of five engineering firms, responsible for planning and design of the entire sewage system upgrade, services during construction, cost and schedule control, and claims mitigation. At the peak of the Program, CH2M HILL managed a work force of 650 people from 88 engineering and technical firms. During this same period, the construction work force peaked at 1,200 people under 75 active construction contracts. CH2M HILL's contractual responsibilities were carefully spelled out in its contract with the MMSD. Figure 1 shows that the contract relationship between CH2M HILL and the MMSD, as well as the contractual relationship between the MMSD and its contractors, was a traditional one.

Fig. 1.

Because of the magnitude of construction and the hazards of underground construction in particular, safety responsibilities were carefully spelled out in both CH2M HILL's contract and in each of the contracts between the MMSD and the contractor. The contracts made clear that CH2M HILL's responsibilities included properly training its own staff, review of and adherence to the contractors' safety programs, and reporting safety concerns to the MMSD and the various contractors. By express disclaimer, however, CH2M HILL was precluded from taking direct action against a contractor and had no authority to stop the contractor's work. The contractors' contracts, by contrast, expressly placed responsibility for safety on the contractor. Each contractor was given sole responsibility for the means and methods of construction, including health and safety. In addition, the contractor was advised that periodic visits by the engineer were for the MMSD's benefit, but that such visits would not diminish in any way the contractor's responsibility for health and safety.

THE HEALY CONTRACT

In 1988, S. A. Healy was hired to construct a two-drive, near surface tunnel, two miles long, for a lump sum of $12 million. Consistent with

other construction contracts let by the MMSD, Healy was given sole responsibility for the means and methods of construction, and for the health and safety of its workers and any personnel on the construction site.

Earlier in 1988, another contractor had encountered methane during underground construction approximately one mile from the site where Healy was to begin its work. As a result of CH2M HILL's subsequent investigation, a contract modification was issued to Healy dated April 5, 1988. In anticipation of potential methane in Healy's tunnel, the modification required Healy to ventilate the tunnel 24 hours a day, install particular fans for the main ventilation system, and engage in continuous monitoring for methane. Under applicable government standards for underground construction, Healy's monitoring equipment needed to provide a warning if the methane levels reached 10 percent of the Lower Explosive Limit (LEL), and shut down Healy's tunnel boring machine (TBM) if methane reached 20 percent LEL. The TBM had to meet specified requirements, and Healy had to use explosion proof equipment and supplies in various places in the tunnel. Finally, Healy was instructed to develop an extensive evacuation and recovery plan to protect its employees in the event of encountering methane.

Healy and two other underground contractors were paid for the costs of implementing the April 5, 1988 modification. CH2M HILL's responsibility was to ensure that the contractors implemented the modification and that the contractors were paid for the required changes.

THE ACCIDENT

In early November 1988, Healy encountered methane during construction. All of the monitoring equipment worked exactly as planned, and Healy was able to successfully evacuate and reenter the tunnel.

Shortly after 7:00 a.m. on November 10, the methane sensors sounded again and the tunnel boring machine shut down. According to subsequent investigations, the tunnel was successfully evacuated. For reasons which are still not clear, however, three of Healy's employees reentered the tunnel in less than the one hour required by the contract. The three employees were Healy's top three people with safety responsibility, including Healy's safety director. Shortly after reentry, an explosion occurred killing all three employees. CH2M HILL was not on site at the time of the explosion, nor had CH2M HILL been notified when the methane sensors sounded.

THE LEGAL PROCEEDINGS

The explosion triggered five legal proceedings involving Healy and CH2M HILL. First, the local District Attorney began a criminal investigation under state law. After reviewing the contractual terms, interviewing Healy and CH2M HILL personnel, and investigating the facts of the explosion, the District Attorney's office decided to prosecute Healy, but not CH2M HILL. Healy was found liable for two counts of criminal negligence, each carrying a $10,000 fine. Healy was cited for failure to follow its own evacuation and reentry plan, and its failure to deenergize the tunnel in accordance with the health and safety plan.

Second, the U.S. Attorney's office began its investigation for violations of federal criminal law. Again, after investigation and interviews, the U.S. Attorney's office declined to prosecute CH2M HILL, but successfully prosecuted Healy for its misconduct. Healy was found liable for three counts of violating Federal safety regulations, each carrying a $250,000 fine. Healy was cited for failure to use explosion proof equipment,

failure to shut off the power after methane was detected, and failure to properly train its workers.

Third, the estates of the three deceased Healy employees filed wrongful death actions against Healy and CH2M HILL. Because Healy's contract required it to indemnify and defend CH2M HILL for Healy's own negligence, CH2M HILL successfully tendered the defense of the cases to Healy's general liability insurance carrier. The three cases were settled without trial for over $750,000.

Fourth, the Occupational Safety and Health Administration (OSHA) issued citations to both Healy and CH2M HILL for willful misconduct. Healy was issued 67 citations, each carrying a potential $10,000 fine. At trial, Healy was found liable for 49 violations, resulting in a penalty of $318,500 ($6,500 per violation).

CH2M HILL was issued 47 citations, each carrying a potential $10,000 fine. Trial was held before an Administrative Law Judge (ALJ) in May-June 1992. All citations against CH2M HILL were dismissed in a decision dated August 25, 1993. The ALJ's 23 page decision reviewed CH2M HILL's contract with the MMSD, how CH2M HILL carried out its contractual responsibilities, and the facts of the methane explosion. The ALJ concluded that CH2M HILL had not engaged in "construction work" as defined under the Occupational Safety and Health Act, and that CH2M HILL did not have health and safety responsibilities at the construction site. Therefore, the ALJ concluded that the construction standards under which CH2M HILL had been cited were inapplicable and that the citations should be vacated.

Fifth, Healy sued the MMSD and CH2M HILL to recover the costs of reentering and completing the tunnel. Despite the prior criminal liabilities, Healy alleged that the explosion and its aftermath caused OSHA to reclassify the tunnel and treat it as a greater hazard, forcing Healy to incur additional costs. The case was settled before trial.

The costs to CH2M HILL of these five legal proceedings cannot be accurately estimated. In addition to the attorney's fees and expert witness costs (in the hundreds of thousands of dollars), CH2M HILL spent substantial amounts of internal time defending these claims, faced extensive adverse publicity both in Milwaukee and around the country, and suffered lost opportunity costs.

Legal Issues (From the Engineer's perspective)Two legal issues are fundamental to an understanding of the lessons CH2M HILL has learned from the OSHA case. The key to determining liability on a construction site revolves around the issue of who "controls" the construction site. Resolving this issue depends on applicable legal precedents, the governing contractual language, and the facts of each case.

The first issue is whether the firm is "engaged in construction work" as defined under 29 C.F.R., Part 1926. In general, the legal precedents have established that a firm is not engaged in construction unless: (a) there is physical labor that is actual construction work (e.g., erection, modification, or repair of a structure) or physical labor that is an integral and necessary part of construction work; or (b) an employer substantially supervises the physical work of construction. For a detailed discussion of applicable legal precedents in this area, see two companion cases: Simpson, Gumpertz & Heger, Inc., 15 BNA OSHC 1851, 1992 CCH OSHD 29,828 (No. 89-1300, 1992) and Kulka Construction Management Co., 15 BNA OSHC 1870, 1992 CCH OSHD 28,829 (No. 88-1167, 1992).

The second issue, of particular importance to CH2MHILL's defense of the OSHA citations, is whether a design professional's rendering advice to a contractor constitutes construction work. The seminal case in this area is Skidmore, Owings & Merrill, 5 BNA OSHC 1762, 1977-1978 CCH OSHD 22, 101 (No. 2165, 1977). The key issue is the authority to control the contractor's work, including the authority to stop work, the authority to stop payments, and the authority to reject non-conforming work. That authority may be express authority (authorized specifically under the contract), or apparent authority (when employees of the firm take actions which demonstrate control over the contractor).

Those who work in the construction arena must understand that there is potential exposure to OSHA regulation in four distinct circumstances:

Your firm is in control of a construction site, and your employees are exposed to a hazard.

Your firm is in control and another firm's employees are exposed to a hazard.

Another firm is in control of the site, but your employees are exposed to hazards as a result of their duties.

Other employees or visitors to the site are exposed to a hazard due to your firm's failure to comply with safety standards.

Although contract language is critical (and was pivotal to CH2M HILL's defense of the OSHA citations), contract language is not necessarily determinative. Employees on a site may act contrary to the express language of a contract (e.g., ordering the contractor to stop work), or employees may be exposed to a hazard when they do not follow a contractor's health and safety plan. Even with contractual protection (e.g., an indemnification clause running from the contractor to the firm), there may be protection from civil exposure, but there is no protection from criminal conduct or OSHA regulation.

LESSONS LEARNED

The following are 10 lessons CH2MHILL learned from the various legal proceedings, primarily defense of the OSHA citations. The lessons come from the engineer's perspective on a construction site, but the guidance on health and safety issues is applicable to any firm working in construction.

Lesson 1: The Language In All Contracts Is Critical

Before undertaking construction work , all applicable contracts need to be carefully reviewed. This includes not only your firm's contracts, but other contracts which may directly or indirectly define how your work is to be performed. As noted above, the key is who has control over the construction site. The roles and responsibilities of all who visit or work on the site must be carefully defined, and other project documents should be reviewed to avoid inconsistencies.

For example, in the Milwaukee OSHA case, there was consistency between the contract CH2M HILL had with the MMSD and the contract between S.A. Healy and the MMSD. In both cases, the contract language emphasized that CH2M HILL's periodic visits to the construction site did not supplant the contractor's responsibility for health and safety. On the other hand, various internal CH2M HILL documents used terms like "construction manager" to define CH2M HILL's role during construction, and this language suggested (at least to OSHA) that CH2M HILL's responsibilities included control of the contractor in some aspects.

Lesson 2: Conduct On The Site Must Be Consistent With The Contract Documents

No matter how carefully drafted the contract documents are (Lesson One), each employee must act consistent with the contractual responsibilities. As noted above, an engineer's employee may not have express authority granted in the contract, but if the engineer's employees order the contractor to stop work, the contractor may act in accordance with that directive, giving the engineer apparent authority over the contractor's work.

For example, an engineer's employee may notice that the contractor is not acting in accordance with its own health and safety plan. The natural tendency would be to point out the problem and perhaps even stop the work until the situation is remedied. Therein lies a potential "Catch-22." On the one hand, there is potential OSHA exposure if the contractor is not stopped, and a hazard exposes your employees to potential danger. On the other hand, interfering with a contractor's work without the authority to do so can incur other legal liabilities for acting outside of the contract.

Normally, the engineer's contract addresses this situation, directing the engineer to bring any deficiencies to the owner's attention so that the owner can stop the contractor's work if necessary. Although this appears to be a somewhat cumbersome procedure, it clearly follows the defined roles in the contract among the owner, the contractor, and the engineer.

Lesson 3: Contemporaneous Documentation Is Imperative

Whenever there is a potential safety hazard, the conduct of all parties should be carefully documented at the time of the incidents. The key to success is making the documents objective (i.e., stating only the facts in a clear manner, including who was there, what happened, what was done, etc.) rather than subjective (i.e., attempting to analyze what happened or who was to blame). The best guideline to follow in drafting any document on a construction site is to assume that a document will be made public, either on the front page of the local newspaper or marked as an exhibit during trial.

In the Milwaukee case, CH2M HILL faced both of these circumstances. One of the documents marked by CH2M HILL was reproduced on the front page of the local Milwaukee paper. On its face, the document appeared to show that CH2M HILL had directed the contractor on which safety equipment should be placed in the tunnel. In addition, numerous documents drafted by CH2M HILL both before and after the explosion were introduced as exhibits in the trial. Fortunately, these documents had been carefully drafted and, in many cases, reviewed by attorneys to insure that they did not expose CH2M HILL to legal liability.

A further caution is important here. One should not assume that a document will remain private, even if marked "Confidential." The only documents which are generally safe from exposure are those which are subject to the attorney-client privilege, i.e., those documents which seek or provide legal advice.

Lesson 4: Control Must Be Given To The Party With The Requisite Education, Training , And Experience

Because the legal precedents establish that the person in "control" of the site has health and safety responsibilities, the definition of control is critical in the contract documents (see Lesson 1) and in the conduct of all parties on the construction site (see Lesson 2).

In the traditional construction relationship, the engineer has historically not had the requisite education, training, or experience to make the necessary health and safety determinations on a construction

site. That role has been given exclusively to the construction contractor. On the Milwaukee tunneling program, S.A.Healy was selected as the tunneling contractor because of its prior experience in this arena, and the contract language was consistent with that experience. CH2M HILL, by contrast, had limited experience in health and safety issues on construction sites, except in an observer capacity on behalf of an owner.

Lesson 5: Even If Not In Control, All Those On Site Need Minimum Health And Safety Training

Because of the extended nature of the Milwaukee Water Pollution Abatement Program, CH2M HILL employees with roles during construction were given a general health and safety training course. In the training, it was emphasized that the contractor's contract controlled conduct on construction sites and that CH2M HILL's role was to provide services on behalf of our client, the MMSD. Employees were advised to be aware of the contractor's health and safety plan on each construction site and to follow the contractor's guidance on health and safety issues. In addition, employees were advised that, except in extreme circumstances (e.g., a case of imminent danger with immediate exposure to serious injury or death), CH2M HILL employees were not to interfere with the contractor's work. If a hazard was noticed, the appropriate procedure was to notify the MMSD in writing, with a copy to the involved contractor.

In the circumstances surrounding the methane explosion, OSHA argued that CH2M HILL's prior conduct (in particular, the contract modification in April 1988) gave CH2M HILL control over the site. This argument was tenuous, however, because CH2M HILL was not present on the day of the explosion, nor did CH2M HILL have any involvement in the decision to reenter the tunnel after the methane sensors sounded.

Lesson 6: Everyone Has A Different Perspective Of Roles And Responsibilities On A Site

As noted above, responsibilities of all parties must be clearly spelled out in the contract documents (Lesson 1) and adhered to by all persons on a site (Lesson 2). The perspectives of who had what responsibilities, however, will change if something serious goes wrong. First, the owner relies heavily on the engineer as an educated, experienced "professional," as the "eyes and ears" of the owner on site, someone who "ensures" that the contractor will adhere to the plans and specifications. Following the methane explosion, the MMSD did its own investigation to determine whether CH2M HILL could or should have done anything to prevent the explosion. One of their critical concerns was whether CH2M HILL had properly inspected to ensure that Healy had installed explosion proof equipment and then monitored Healy's use of the equipment. The ALJ's decision, however, clearly recognized that CH2M HILL's responsibilities did not go so far. Rather, CH2M HILL simply had to ensure that the constructed project generally conformed to the plans and specifications, not to oversee all of Healy's activities.

Second, the contractor's perspective is that the engineer should stay clear of the means and methods of construction (including safety). When a serious claim arises, however, it is not uncommon for a contractor's attorney to name the engineer as a defendant, alleging that the engineer had responsibility to prevent the accident from happening. Fortunately for CH2M HILL, Healy's attorneys did not take such a tack. Healy's personnel testified that CH2M HILL had carried out its responsibilities in an appropriate manner, and that the responsibility for health and safety was solely Healy's.

Finally, OSHA perspective is the most troublesome. Despite the clear language in both CH2M HILL's and Healy's contract, OSHA consistently argued throughout the legal proceedings that CH2M HILL had an express role in health and safety issues long before the explosion. OSHA relied on various documents CH2M HILL had produced in generating the April 1988 contract modification to argue that CH2MHILL was in fact "engaged in construction work." OSHA alleged that the activities in obtaining the methane sensing equipment, for example, required CH2M HILL to "substantially supervise" Healy's work. Again, however, the ALJ rejected OSHA's arguments.

Lesson 7: Construction Projects Are Inherently Risky, And The Legal System May Not Mitigate Those Risks

Owners on public works projects (especially government agencies) are often required to select the contractor with the lowest bid who may or may not be the most qualified or have the past experience. In such circumstances, there are inherent risks to all parties engaged in the construction project, including the engineer. In fact, the owner may expect that the engineer take a more visible role in overseeing the contractor's activities, precisely because of concerns about liability. In addition, contractors, stuck with low bids, have incentives to cut costs whenever possible, and unscrupulous contractors may attempt to cut costs in the safety arena in order to maximize profits. Again, the owner's perspective may be that the engineer should oversee these activities to ensure that the contractor does not take such steps.

Finally, the worker's compensation laws are currently designed to give injured employees certain remedies without proof of fault, yet the same laws allow employees to seek additional relief from others (e.g., the owner and the engineer). In the Milwaukee case, this is precisely what allowed the estate of the deceased employees to sue CH2M HILL. After recovering the statutory amount allowed by the worker's compensation laws from Healy, the attorneys then sued CH2M HILL in order to recover additional sums.

Especially in circumstances of severe injury or death, the legal system is not inclined to leave injured employees without a full and "fair" remedy. If a judge or jury determines that the injured employee did not receive "fair" compensation under the worker's compensation law, there is a greater tendency to assess blame to other parties.

Lesson 8: There Are No Clear GuidelinesHire Competent Experts And, If Necessary, Lawyers

Design professionals and others involved with health and safety issues are increasingly being asked to walk a fine line. Contractors are often adamant that the design professional should not interfere with the means and methods of construction, including safety; owners, on the other hand, want to ensure that the construction project goes smoothly, and that the design professional take a more active role in overseeing the contractor's activities. When the responsibility for "control" is blurred in this manner, there are no clear guidelines as to what the courts or OSHA will do. Accordingly, seeking competent legal advice is often imperative.

In the months following the methane explosion, there were public statements by OSHA officials to the effect that design professionals should have an increasing responsibility for construction site safety. From CH2M HILL's perspective, this meant that the OSHA citations became something of a test case for the OSHA administration. OSHA argued

throughout the legal proceedings that general legal precedents involving design professionals and contractors were simply not applicable; instead they argued that prior OSHA cases demonstrated that CH2M HILL's responsibilities included oversight of Healy.

Subsequent to the methane explosion, the Occupational Safety & Health Act itself was amended to increase substantially the fines and penalties. In such circumstances, the need for competent legal and expert help is even more important.

Lesson 9: The Greater The Injury, The Higher The Profile And The Greater The Exposure

Accidents involving serious injury or death are high profile, media intensive, legally risky events. Following the methane explosion, there was extensive coverage in local newspapers, radio, and television, including editorials about CH2M HILL's role in the events leading to the explosion.

The best advice is to get competent help early in the process to mitigate such problems. This may require internal management independent of the project, independent technical consultants with specialized knowledge (e.g., tunneling regulations, standard of care for design professionals in construction, OSHA regulations), or lawyers who are professionally knowledgeable.

Lesson 10: There Are Ambiguities In The Osh Act, The Osha Regulations, And The Applicable Case Law Which May Result In Greater Exposure

Those engaged in work which is subject to the OSH Act need to recognize the ambiguities in the act itself, the applicable OSHA precedents, and the OSHA regulations (part 1926). Throughout the legal proceedings, CH2M HILL was consistently faced with these inconsistencies and ambiguities, despite what we believed were clear contractual responsibilities among CH2M HILL, S.A. Healy, and the MMSD.

CONCLUSION

Firms involved in construction must recognize that the construction industry in general is changing. More and more owners in the marketplace are seeking firms who can provide design-build experience, engineer-procure-construct (EPC) experience, or what is loosely described as "one stop shopping." The traditional consulting work which has long been the main stay of firms like CH2M HILL is diminishing, replaced by these other forms of contracting.

Along with these changes, there will be significant changes in the area of health and safety as well. The lines of demarcation between a traditional design professional's responsibilities and a contractor's responsibilities with regard to health and safety are becoming more and more blurred. Those who continue to pursue construction projects will necessarily be required to have a higher degree of expertise in health and safety issues to continue to meet their clients' needs.

CH2M HILL has learned a great deal about health and safety issues in the painful aftermath of the Milwaukee methane explosion. We have learned from our outside lawyers and expert witnesses; we have learned from the court proceedings on the OSHA citations; we have learned from our clients what their expectations are with regard to our role on construction sites; and we have learned from our project managers and project personnel how difficult it is to separate roles and responsibilities with regard to site health and safety during the course of construction.

In order to continue to meet our clients' needs, we will continually engage in improvement of our health and safety programs and continue to

educate our employees about the importance of understanding and adhering to our contractual responsibilities.

BENEFITS OF A CUSTOMIZED HEAT STRESS PROGRAM ON JOHNSTON ATOLL

Elizabeth Hill
Raytheon Services Nevada
Johnston Atoll Operations

ABSTRACT

Base reconstruction in the aftermath of Hurricane John presented a unique opportunity to monitor employee heat strain on Johnston Atoll (JA). Employees worked 12-16 hour days performing heavy construction work during the September 1994 restoration, including work in protective clothing and respirators, and in confined spaces. From a maintenance contractor's perspective, hurricane restoration activities presented a worst-case scenario for employee heat exposure. Published data on work-rest regimens were highly restrictive and not feasible. Safety and Health (S&H) staff collected environmental temperature indices (wet-globe) to determine environmental conditions, and biological samples (oral temperature, urine specific gravity, heart rate) to determine employee heat strain. A customized work-rest regimen was then formulated for JA's workforce. Education and awareness training was an integral part of the heat stress program, with the goal that individuals developed awareness of how they are felt (heart rate, sweat rate, dizziness, cramping, thirst), and of their need to drink plenty of water and take regular breaks. Training was informal, most information was exchanged while S&H staff visited the worksite to collect samples. The customized heat stress program provided the following benefits: sensible work-rest regimens were made in accordance with the heat tolerance of the workforce; heat-related illness did not occur; work was accomplished in a reasonable time frame; employees perceived they were cared for.

INTRODUCTION

Heat stress is a potential health hazard for DOE contractor employees in many different working conditions and circumstances. Base restoration in the aftermath of the August 1994 Hurricane John, presented a unique opportunity to monitor employee heat strain on Johnston Atoll (JA), a small Pacific island group located 800 miles southwest of Hawaii, operated by DOE/DNA/DOD. From a maintenance contractor's perspective, hurricane clean-up and restoration work, which occurred from late-August through mid-October 1994, presented a worst-case scenario for heat exposure in general maintenance and construction.

JA's climate is generally hot and humid, with steady tradewinds. August and September traditionally are months with the highest air temperatures of the year, and are times when tradewinds die down. During JA's restoration, Safety and Health (S&H) personnel monitored environmental conditions using a wet-globe thermometer (botsball), and collected biological measurements on employees (oral temperature, heart rate, urine specific gravity) to determine heat strain. These data were used to formulate a customized work/rest regimen that had the objective of preventing heat-related illness, and, accomplishing site restoration in a timely manner.

WORK ACTIVITIES AND CONDITIONS

Work activities performed during the restoration included:

roof repair and resurfacing (hot tar);
utility repair (power, water, sewer, communications);
facility demolition, renovation, and repair;
asbestos removal and repair;
debris pick-up and disposal.

Work conditions are described as follows:

12-16 hours workdays, six to seven days per week;
working outdoors in full sun performing manual labor;
working in full sun on asphalt roofs spreading hot tar;
working in confined spaces;
working indoors and outdoors wearing protective clothing and respirators;
working indoors, without operative ventilation systems.

ENVIRONMENTAL CONDITIONS

Environmental temperature indices such as the wet-bulb globe temperature (WBGT) have traditionally been used to determine employee work/rest regimens, even though these indices have not always correlated well with human responses to heat (1,2). Other environmental indices include the wet-globe (botsball). The botsball index combines the physical parameters of air temperature, humidity, wind, and radiant energy from heated surfaces.

To avoid heat stress, the American Industrial Hygiene Association (AIHA), the American Conference of Governmental Industrial Hygienists (ACGIH), and the U.S. Army recommend work/rest regimens that are based on WBGT indices. WBGT indices easily convert to wet-globe (botsball) indices using the following conversion formula:

(1) WBGT = 0.0118B - 0.560B + 54.9F Where B = botsball temperature index;
F = degrees Fahrenheit.

TABLES I - III represent the AIHA, ACGIH, and the U.S. Army's work/rest regimens, converted to wet-globe temperature (botsball) indices, in degrees Fahrenheit (F).

TABLE I
TABLE II
TABLE III

Wet-globe (botsball) temperature indices on JA during the restoration ranged between 78 and 90 degrees Fahrenheit (F). Botsball temperature indices varied throughout the day. Average index values during the restoration were:

inside buildings 81.7 F;
inside confined spaces 82.3 F;
outdoors 84.1 F;

Based on information in Tables I-III, botsball indices in the low to mid 80's (F) call for implementation of work/rest regimens, rather than allowing continuous work with short hourly breaks. Given the average botsball readings during the restoration, the recommended work/rest regimens were not feasible for two reasons:

1. site restoration and critical military operations would not be accomplished in an acceptable timeframe;
2. the established work/rest regimens were not well accepted by the JA workforce, who maintained they were used to the conditions.

HEAT STRESS SURVEY AND SAMPLING STRATEGY

Based on the AIHA recommendations for continuous work, S&H staff initiated the survey under a regimen of a 10 minute break after every

hour of work. Breaks were taken in the shade, and cold water and electrolyte drinks were available at all times in the work area. S&H staff conducted environmental and biological monitoring to determine employee heat tolerance, and to establish a feasible work/rest regimen for the JA workforce, one that would meet both the mission's timeframe, and with employee acceptance.

Individuals were monitored for internal (oral) temperature, external body temperature (patch), heart rate, and urine specific gravity (USG). Environmental temperature indices (botsball) were also recorded. Samples were collected on 17 different days, in a variety of locations, on different employees, at different times throughout the day (see attached data).

Employees were counseled on the effects of heat stress and made aware of the body's warning signs (sweating, prickly heat, headache, muscle cramps, etc). They were allowed to take additional break time when they felt the need to rest, cool off, and replenish fluids.

DESCRIPTION OF MEASUREMENTS

BOTSBALL THERMOMETER A direct reading wet globe thermometer that combines air temperature, humidity, wind, and thermal radiation into a single index value (degrees F) that reflects environmental conditions.

ORAL THERMOMETER A direct reading internal body temperature indicator (degrees F). In general, an oral temperature > 100 F may indicate heat strain.

TEMPERATURE PATCHA direct reading external body temperature indicator that is supposed to correlate with core body temperature. Temperature patches are affixed to the forehead and a colorimetric change indicates core temperature (F).

URINE SPECIFIC GRAVITY A direct reading checkstrip is immersed in a fresh urine sample; a colorimetric change indicates specific gravity. In general, USG > 1.027 grams per cubic centimeter indicates dehydration, a symptom of heat strain.

HEART RATE A direct reading of the number of heartbeats per minute.

At rest, most men have a heart rate of 60-70/women have a heart rate of 68-78. A working heart rate greater than 100 for men/110 for women, may indicate heat strain.

HEAT STRESS SURVEY FINDINGS

During the survey period, most employee core body temperatures remained normal (98.6 F +/- 1). When a high oral temperature or heart rate was measured, the individual was removed from the work area and allowed quiet time to recover. If/when an employee developed a heat rash, they were advised to shower/change clothes several times per day. Employees found that wet-wiping of their head/upper body was also an effective cooling measure.

Temperature patch readings did not provide useful data in this survey. There was not good correlation between the patch temperature and the oral temperature, so their use was discontinued.

When high USG's were encountered, individuals were counseled on taking water or electrolyte drinks, even if they did not feel thirsty, and

encouraged to get proper rest. They were advised that they could better rehydrate if they continued drinking water throughout the day and evening, and avoided substances containing alcohol and caffeine.

A common premise in heat stress programs is that people know when they need to take a break. During the survey, it was found that employees were so focused in their work that they did not take enough breaks, or enough fluids. Over the course of sampling, employees were shown when they were dehydrating, even though they said they felt fine. This surprised some employees and opened the door to discussion, a valuable part of awareness training.

The data showed there was an initial period when employees just returning to JA show higher oral temperatures, USG's, and heart rates, than acclimatized workers. This is consistent with findings described in the literature (1,2). This means that newcomers/returning workers need acclimatization time, about 10 days. During the acclimatization period, there needs to be a more restrictive work/rest regimen, and employees need to be counseled on heat stress awareness.

The survey indicated that employee awareness and education played a paramount role in a practical and effective heat stress program. The goal of a practical heat stress program is to make employees aware of the hazards, aware of the warning properties, aware of what their bodies are telling them, and aware that rest and water intake provide balance to the stresses they are subject to in the workplace. Information in the heat stress awareness program was provided during informal workplace conversations, which was a good way to reinforce the taking of breaks. Based on the data, the regimen used in this survey was appropriate to the heat tolerance of JA's acclimatized workforce, and was effective in preventing heat-related illness.

DISCUSSION

Sampling instruments used in this survey were inexpensive, portable, and provided instantaneous direct readings. Botsball thermometers cost about $100. Oral thermometers and urine check strips can be obtained at most drug stores for a nominal fee. Heart rate can be measured by taking a pulse and using a wristwatch with a second hand.

In the process of collecting heat stress data, S&H personnel spent time on the worksite talking with employees about their work, their sample results, how they felt, etc. This fostered an atmosphere of caring in the workplace. The measurements provided instantaneous feedback to employees that was meaningful to them, letting them know how their bodies were responding to their environment and what they needed to do to take care of themselves.

Employees were encouraged to be self-regulating with respect to taking breaks/fluids. Some employees felt empowered when allowed to be self-regulating. Malingering complaints were not a problem, instead, JA's employees had to be reminded to take more breaks.

When botsball or WBGT indices reach the low 80's, line operations can be informed of the need to implement a regimen that includes hourly breaks, and to provide cold water/electrolyte drink at the worksite. Tasks can be evaluated qualitatively for energy expenditure demands.

Line operations can then present heat stress awareness information during their regularly scheduled safety meetings, and S&H staff can visit the worksite and talk with employees about the key points of the heat stress awareness program and/or collect biological measurements. Employees performing tasks with significant energy expenditures, or with greater

potential for heat strain, can be individually counseled on heat stress symptoms and preventive measures.

Using the biological monitoring approach and measuring employee heat strain, the workforce tolerance to environmental conditions can be determined, and feasible work-rest regimens can be established. WBGT or other environmental indicators can be used qualitatively as a trigger mechanism for conducting biological monitoring, implementing heat stress training and establishing work/rest schedules.

This data applies to maintenance and construction activities, but use of biological monitoring to establish a feasible working schedule has potential for other applications. For example, S&H staff also used this formula to monitor non-typical operations, such as projects where employees have to wear protective clothing that increases their heat load (tyvek, anti-C's, etc).

CONCLUSIONS

1. The most valuable data to assess employee heat strain was found to be oral temperature, USG, and heart rate.
2. It was found that employees need a few weeks to acclimatize to changes in their physical environment, even if they have only left the environment for a few weeks, such as during vacation time.
3. Employee education and awareness is important in an effective heat stress program; informal workplace conversations are a valuable forum for information exchange.
4. A regimen for continuous work with hourly breaks was implemented and tested with biological monitoring. Biological monitoring showed employees when they needed to rest/replenish fluids, and was successful in preventing heat-related illness. Environmental temperature indices can be used to indicate when a biological monitoring program may be of benefit.
5. Temperature patch readings did not provide useful data in this survey.

THE PU-ISSUE: GOING MOX OR ALTERNATIVE SOLUTIONS?
MATERIALS SCIENCE ASPECTS

ABSTRACT
At present, an excess of plutonium exists worldwide, due to reprocessing of spent commercial LWR fuel and to Pu arising from dismantling of nuclear warheads, while the construction of fast reactors is delayed. If the reprocessing capacity available after 2000 is fully used the amount of Pu from civilian spent fuel could reach 20 t Pu/yr in 2005. The increase of the inventory from dismantled warheads presently being discussed is 10 t Pu/yr from 1996 to 2005 thus making available 100 tons of fissile Pu. The decision of how to store or how to recycle this Pu is mainly a matter of politics. In the present paper, the materials science aspects of three options are discussed: going MOX, alternative fuels, or vitrification. Work in the materials research of these three fields has been performed at the European Institute for Transuranium Elements for more than two decades.
Going MOX: present and near-future MOX fabrication capacities existing in Europe and Japan are sufficient to accommodate between 15 t Pu/yr (lower limit) and near to 25 t Pu/yr (upper limit). MOX fuel fabrication and Pu recycling are becoming a mature industrial activity. The extensive irradiation experience with MOX fuel is positive. To make (conventional, hence UO2-based) MOX fuel more attractive and to achieve a high Pu disposition rate, the fuel cycle costs should be reduced and high core loadings should be achieved. This asks for high burnup in a once-through cycle with automated or dust-free fuel fabrication, e.g. with the sol-gel process.
Alternative fuels: An inert matrix completely free of U-238 (e.g. spinel MgAl2O4, CeO2 or others) containing e.g. 5 % Pu allows burn-out of Pu to a large extent. These inert matrices can also be used for transmutation of the minor actinides (Np, Am, Cm), provided they fulfill a number of criteria: their thermal conductivity and their mechanical properties should be similar or better than those of UO2, they must be compatible with clad and coolant, fabrication procedures must exist and, importantly, they must show an acceptable behavior against radiation. Based on measurements of these properties, suitable matrices can be selected.
Vitrification: A large series of actinide-containing borosilicate waste glasses was produced in the European Institute for Transuranium Elements in the past 20 years. Solubilities of actinides, relevant mechanical, thermal and chemical properties were measured and the effects of radiation damage due to a-decay of the actinides was followed, mainly in curium-doped glasses thus simulating the behavior of HLW glasses for 105 yrs storage, or of glasses containing 7 wt% Pu for up to 2000 yrs storage. This large data base is discussed, as is the possibility of incorporating Pu in suitable ceramics instead of glasses.
INTRODUCTION
The presently existing excess of plutonium can a priori be dealt with by adopting one - or a combination of - three options: going MOX, burn Pu in alternative fuels, e.g. in an inert matrix, or vitrify and bury Pu. The decision on any of these options will have to be made by politics, but should be based on engineering, neutron physics and materials science aspects as well. It is this latter aspect the present paper is concerned with.
Current reprocessing commitments represent arisings of Pu from civilian spent fuel (reactor plutonium, R-Pu in the following) of roughly 15 tons per year up to 2000 and on average of 12.5 tons per year from 2000

onwards. However, if full use is made of the reprocessing capacities existing after the year 2000, this amount might increase to 20 t Pu/yr in 2005. This R-Pu contains typically only about 65% Pu-239. For instance, when reprocessing PWR UO2-fuel with a burnup of 33 GWd/tonne, the isotopic composition is ~ 1.3 % Pu-238, 62.8% Pu-239, 23.5% Pu-240, 8.3% Pu-241 and 4.1% Pu-242 or, at increased burnup in a pressurized water reactor, the composition is 2.6% Pu-238, 54% Pu-239, 24% Pu-240, 12% Pu-241 and 7.4% Pu-242. To the above amount of R-Pu, the dismantling of warheads might add ex-weapons Pu (W-Pu in the following) at a rate of 10 t Pu/yr from 1996 to 2005. W-Pu contains typically 93 % Pu-239, 6 % Pu-240 and 1 % Pu-241. Its critical mass is therefore smaller than that of R-Pu, the spontaneous neutron emission rate and the heat production are significantly smaller and it therefore deserves particular attention to guarantee proliferation resistance, as well as an expeditious decision on the strategy of its dispositioning. Given the present unavailability of fast reactors and of accelerator-driven reactors, there are essentially two ways to effectively prevent W-Pu from being used for warheads production: I) use it as MOX fuel in civilian power plants to bring it to the level of spent fuel, hence converting it to R-Pu grade while, at the same time, mixing it with fission products and keeping open the options of direct disposal in a repository as spent fuel or intermediate storage of the spent fuel for later reprocessing. Using inert matrices rather than UO2-based MOX fuel can increase the disposition rate. Or: ii) dispose of W-Pu without producing electricity by applying a process which causes the material to be inaccessible for diversion, e.g. by blending the Pu with fission products, to vitrify the mixture, as it is done for high level liquid waste from reprocessing, or to solidify it in a ceramic matrix and to dispose of the product in a safe, deep geological repository. To increase the proliferation resistance for intermediate storage for option I) and to reduce the storage costs, W-Pu could be mixed with R-Pu. The blend has a higher heat production and a higher rate of spontaneous neutron emission than W-Pu due to the introduction of Pu-238 and of Pu-242, and the higher content of Pu-240. In addition, the higher content of Pu-241 decaying into Am-241 leads to an increase in g-activity and thus to an easier detectability in case of illicit traffic. The emphasis of the present paper is placed on materials science aspects of these options rather than on such strategies themselves. Research on fabrication and materials property studies in the areas of MOX-fuel, inert matrices, vitrification and solidification in ceramic matrices has been performed in the European Institute for Transuranium Elements for more than two decades. In the following, we will concentrate in particular on fabrication and R&D for inert matrices and vitrification, realizing that other aspects such as nuclear safety, licensability and economic viability are of large importance as well. Frequently, e.g. in neutronic considerations, the non-fissile, non-fertile matrix is treated as inert to the extent that its materials properties are not considered at all. This is particularly true for its radiation stability, which will therefore be treated in more detail in this paper.

UO2-BASED MOX FUEL

Fabrication and irradiation experience of Pu-recycling as UO2-based mixed oxide (MOX) fuel, i.e. UO2 with 3 - 5% PuO2 exist now for about 30 years. For instance, in Germany, Pu-recycling started in BWRs (Kahl) in 1966 and in PWRs (Obrigheim) in 1972. In Belgium, it started even earlier in 1961. The fabrication experience covers rather different Pu-compositions, from

Pu from reprocessing MAGNOX fuel with a high content of Pu-239 to the Pu mentioned above from reprocessing of LWR fuel. Through the years, the fabrication techniques were optimized to improve the early mechanical blend MOX fuel, in order to reduce hot spot problems due to PuO2-rich inclusions in the fuel and to achieve a better solubility in HNO3 in case reprocessing is to be done. As examples, the ammonium uranyl plutonyl carbonate (AUPUC) process of powder preparation and the optimized co-milling (OCOM) process were developed and tested by Siemens, and the micromized masterblend (MIMAS) process was developed and tested by Belgonuclaire. Satisfactory Pu-solubility (>99%) already in the unirradiated pellets was achieved and a good irradiation performance could be proven (1, 2). The existing and projected MOX fuel fabrication facilities are summarized in Table I. They are all situated in Europe and in Japan. The plants at Hanau are mentioned without numbers because of the known political problems. Facilities originally built to produce MOX for fast reactors can be included in this consideration, since modifications to change from FBR MOX (typically 20 - 25% PuO2) to LWR MOX can be introduced, and dual purpose production lines are also feasible. The table shows that the MOX fuel fabrication capacity may be able to catch up with Pu-arisings when considered globally, though the stockpile will temporarily increase if W-Pu becomes available at the rate of 10 t/yr for 10 years, the amounts depending also on the Pu-content used for the MOX fuel. The equilibrium between production and consumption of Pu would probably be achieved around 2015 rather than 2005 for R-Pu alone.

Table I

To achieve a good homogeneity, i.e. a solid solution of PuO2 and UO2 in the MOX fuel, coprecipitation could be used, or the sintering program could be modified, e.g. by varying the oxygen potential during the sintering process. Increasing the oxygen potential increases interdiffusion rates (3, 4). A subsequent reduction step at lower temperatures can be used to bring the material back to the stoichiometric composition, since oxygen diffusion in UO2 and in MOX is much faster than U and Pu (inter)diffusion, e.g. D0/DM 108 at 1200C, M = U or U+Pu. To make MOX fuel more attractive, fabrication costs have to be kept low, and, for R-Pu, the increasing concentration of the g-emitter Am-241, formed by decay of Pu-241 with a half-life of 14.9 years, has to be taken care of. If Am-241 is not separated from R-Pu stored for some time, a dust-free fabrication process is advantageous. Such a process exists and has been demonstrated: the sol-gel process, or the gel-supported precipitation process (5).

The irradiation performance of MOX fuel is also very encouraging and satisfactory (1, 2, 4). Experience exists from experimental irradiations and from many MOX fuel assemblies loaded in thermal reactors in Japan, Germany, France, Belgium, Switzerland and USA. Some of these went to extended burnups. These assemblies and transient-tested MOX fuel showed a dimensional behavior comparable to that of UO2 fuel. Very few fuel rod defects have occurred, and these were neither specific for MOX fuels nor did they have their origin in the use of MOX fuel. Some features of the performance deserve further study, e.g. the fission gas behavior in Pu-rich MOX inclusions, the behavior of such MOX agglomerates at the pellet surface if they are not fully surrounded by the UO2 matrix etc. Also, though there is no significant difference between MOX and UO2 fuel for fission gas release at comparable power densities and power histories, up to 40 GWd/tM, the MOX fuel has a greater power at higher burnup because

the change in reactivity with burnup is less than for UO2 fuel. The fuel rod design should allow for the space needed to appropriately accommodate the larger amounts of released fission gas at extended burnups.

As of today, about 35 LWRs are licensed for MOX fuel, most of them in western Europe. For another 25 power stations licensing is underway, usually for reloads with 1/3 MOX fuel. Many more (about 100) power stations are potential candidates to operate MOX fuel since there are no fundamental technical problems for licensing. By adequate design and by suitable distribution of the MOX fuel elements in the reactor core, no adverse effects result on reactor control and operation for the 1/3 MOX option. The higher inventory of Pu and actinides does not affect reactor safety. 100 % MOX cores are also possible when adjustments and changes of core design and equipment for reactor control are made (1).

Going MOX is thus an existing option to significantly reduce stockpiles of either W-Pu or R-Pu, and to reach equilibrium between production and dispositioning to the spent fuel standard. To make this option economically attractive the fuel cycle costs should be reduced: automated, or dust-free fabrication (sol-gel), high burnup fuel, high core loadings are the aims to achieve a high Pu-disposition rate. Comparatively like R&D in materials research is necessary given the advanced state of fabricating and irradiating MOX fuel which exists already today.

ALTERNATIVE FUELS, INERT MATRICES

An inert matrix is a material which replaces conventional UO2. It should not form Pu or other actinides, but otherwise have properties similar or superior to those of UO2. Hence, it should have a high melting point, good thermal conductivity and mechanical properties, and it should be compatible with the cladding and the coolant. Also it should have a low neutron capture cross section to achieve a good neutron economy, and, importantly - but often not considered to the appropriate extent - it should be resistant against radiation (fission, neutrons and a-decay of Pu.). To avoid actinide buildup, all the components of the inert matrix should have atomic numbers significantly smaller than 92.

Since no new actinides are formed, a large degree of burnout can be achieved if irradiation is carried out for a long enough time. This possibility and the advantage of inert matrices are exemplified with a novel proposal (6) to destroy up to 95% of the W-Pu in LWRs while at the same time increasing the proliferation resistance of the spent (inert matrix) fuel by forming high levels of Pu-238 in the small quantity of remaining Pu. As shown in Fig. 1 (left and middle parts), a fuel with an inert matrix and with 2.5% each of W-Pu and W-U (i.e. U enriched to 94% U-235), irradiated for approximately 2000 d together with standard fuel of 900 days lifetime in a PWR shows a burnout of 99.4% of Pu-239. Of the originally added 25 kg W-Pu/t (23.5 kg Pu-239), only about 6% of total Pu-remain. Of this small amount, 28% are Pu-238, 57% are Pu-242, and only 6% (or 100 g) are Pu-239. The isotopic composition of Pu - even if separated from the inert matrix - is very proliferation resistant because of the large content of Pu-238, mainly originating from irradiating the added W-U, and of Pu-242, yielding very high heating rates in excess of 150 W/kg Pu and a neutron emission rate which is a factor of 32 higher than that of W-Pu, respectively (6). The W-U is also transferred into proliferation resistant form since the U-235 content of the small remaining U-mass is only 17%, hence below the 20% level considered proliferation-safe. Furthermore, as shown in the right part of Fig. 1, a

similar irradiation of the inert matrix with 10% R-Pu leads also to a large burnout (7). An LWR with 1/5 of the assemblies being made from such fuel - the remaining part being standard UO2 fuel, can be shown to have a balance between Pu-production and Pu burning (7).
Fig. 1
In such kind of calculations, materials properties of the inert matrix itself are usually not considered. Significant R&D is still necessary to select suitable matrices for given irradiation schedules. Also, improved or unconventional clad materials have to be selected and tested to achieve the desired high burnups. Significant work in this area is presently ongoing in the related field of transmutation of Am and Np in nuclear reactors. If these minor actinides are partitioned from the reprocessing HLW, they can be transmuted by fast neutrons from fast reactors or accelerator-driven reactors, or - usually at a smaller rate - in thermal reactors. Inert matrices are considered for this purpose as well, e.g. in the large international project EFTTRA (Experimental Feasibility of Targets for Transmutation) (8), providing experience and a data base of use for Pu-dispositioning as well.
Materials suggested and fabricated as inert matrices include binary oxides (e.g. Al_2O_3, MgO, CeO_2, ZrO_2), ternary oxides (spinel $MgAl_2O_4$, Zircon $ZrSiO_4$ or monazite $CePO_4$), complex oxides (e.g. PuO_2-stabilized ZrO_2-Al_2O_3-MgO or a two-phased mixture of a fluorite phase (PuO_2-ThO_2, PuO_2-ZrO_2) with Al_2O_3 (9), and binary carbides and nitrides (e.g. SiC, Si_3N_4, ZrN etc.).
Basically, two types of matrices exist, a homogeneous case, i.e. a matrix which forms a solid solution with Pu, e.g. CeO_2, zircon ($ZrSiO_4$) or ZrN. If Pu is not soluble, as in Al_2O_3 or MgO, a heterogeneous fuel is formed with PuO_2 precipitates as a second phase. This resembles to some extent the conditions of the early MOX fuel. For a final selection of suitable matrices, their properties (thermal diffusivity, specific heat, thermal conductivity, mechanical properties, hardness, fracture toughness, absence of chemical reactions with clad and coolant) have to be measured, not only on the matrix alone, but also on the fabricated fuel including Pu. This leads to exclude some of the candidates for specific conditions, e.g. MgO for LWR and CeO_2 for FBRs because of reactions with H_2O and Na, respectively, or to concerns as for stabilized ZrO_2 because of its low thermal conductivity. Furthermore, the solubility in HNO_3 is of interest if reprocessing is foreseen, whereas very low leach rates in ground water are asked for if a once-through option is selected. This, however, is not sufficient since information on the above properties are also necessary for the Pu-matrices subjected to radiation damage. Sometimes, data are available for neutron damage, e.g. for MgO, for Al_2O_3 and for spinel $MgAl_2O_4$. Stability against neutron damage alone is not sufficient, since the inert matrices will also be subjected to a-decay damage (5.15 MeV a-particles and 88 keV U-235 daughter recoil atom in the decay of Pu-239) and fission damage (fission products of 70 to 90 MeV). a-decay occurs following fabrication during storage before and after reactor use, essentially at room temperature when damage recovery is small. To give an example: $(Pu\text{-}239)O_2$ shows a decrease in thermal conductivity of 60% after one year of storage. Fission damage occurs at reactor operating temperatures. Some potential matrices can be shown to be structurally unstable or to swell to a large extent. An example is Al_2O_3 which swells by about 30% under fission fragment impact and which gets amorphous after rather short irradiations 10. As another example, spinel ($MgAl_2O_4$) known

to be very stable under neutron irradiation, the reasons for this stability being understood, swells also under fission product impact and undergoes polygonization, i.e. a state with very small grains is formed, if irradiation is performed at ambient temperature. The behavior is, however, more benign at elevated temperatures, e.g. T>500C.
Work in this field is ongoing and will lead to a selection of good matrices.

VITRIFICATION

Work on incorporation of actinides (Th, U, Np, Pu, Am, Cm) into borosilicate waste glasses and property measurements of such glasses have been performed in the European Institute for Transuranium Elements since 1975 (11). This work was done in the frame of R&D studies to vitrify high level waste from reprocessing of spent LWR fuel. In this HLW, the actinide content is small, i.e. the sum of UO_2, NpO_2, PuO_2, AmO_2 and CmO_2 is < 1 wt.% and can safely be assumed to be in solution. For this work, a number of different waste glasses was used, including the German (simulated) product GP 98/12 and its precursor (see Table II).

Table II

To determine the solubility and/or to observe possible segregation of PuO_2 at higher Pu-contents, the precursor product GP was produced with up to 10 wt.% PuO_2 by mixing the proper quantity of the glass frit with or without denitrated waste solution and with Pu (or also Am) (12). Melting was performed in Pt-crucibles. The resultant glass was pulverized and molten again in graphite crucibles at 1150C. Discs were cut from the glass cylinders produced in this way. Alpha-autoradiographs showed no visible segregation for the highest AmO_2 content used, i.e. 4.9 wt.% AmO_2, whereas very obvious segregation (spots very rich in PuO_2) were seen when 10 wt.% PuO_2 were added. Additionally, a base glass without HLW and the glass with very high HLW loadings, i.e. either 20 wt.% HLW, or 20 %HLW with additionally 10 wt.% Gd_2O_3, were produced with 5wt.% UO_2 or 5wt.% PuO_2, respectively. 80 mm long cylinders were kept molten (1175C) in Pt-crucibles for 25 h. Subsequently, discs were cut from the bottom, the middle and the top section of these rods and analyzed by electron probe microanalysis, epma. These analyses showed the absence of sedimentation of actinides. In contrast, the noble metal particles were enriched in the bottom section.
Glasses doped with 5 wt.% AmO_2 or 3 at% UO_2 were still vitreous with no crystalline phase being present. In contrast, the glasses containing 5 wt.% PuO_2 consisted all of two phases, the major vitreous phase and a minor crystalline phase. In detail

- the base glass contained 4.6 wt.% PuO_2 in solution. The second phase was PuO_2
- the glass with 20% HLW contained less PuO_2 in solution, i.e. 4.4 wt.%, the crystalline phase being again PuO_2
- the glass with 20% HLW and 10 % of the neutron poison Gd_2O_3 showed a very small solubility of only 1.2 wt.% PuO_2 and contained segregated crystalline phases of an (average) composition of $(Pu_{0.68}Ce_{0.2}Gd_{0.12})O_2$.

These solubility values are large compared with the actinide contents in HLW solutions, but they may be of concern for the fabrication of Pu-containing glasses, if fission products (in particular rare earths) are added to these glasses.
Thermal and physicochemical properties and leaching of these and other waste glasses have been measured extensively and the behavior against a-decay damage including He-accumulation and release have been measured

(13, 14). Figure 2 shows the relation between the accumulation of a-decay damage (a-decays/m3) and the storage time for

the test glass containing 1.5 wt.% Cm-244 (lower abscissa)
the same glass containing 7 wt.% Pu-239 (upper abscissa)
typical HLW from reprocessing vitrified in the same glass (upper abscissa).

Fig. 2

The damage studies were terminated at damage levels of 15 to 25x1024 a-decay/m3. A damage level of 15x1024 a-decays/m3 will be reached in the glass with 7% Pu-239 in about 1000 years.

Damage due to a-decay is caused by a-particles and by recoil atoms. a-particles loose 99% of their energy of 5.15 MeV (for Pu-239) by ionization, have a range of ~20 mm in glass and produce only ~200 atomic defects, mainly at the end of their range. The recoil atoms (U-235 in the decay of Pu-239) have an energy of ~90 keV. About 90% of this energy is used to produce 1200 to 1500 displaced atoms thus forming a dense collision cascade along their range of ~25 nm. This type of damage can be simulated with ion implantation techniques. This was done extensively at ITU, in addition to the work with the Cm-glasses. The properties measured were: swelling, leaching, hardness, fracture toughness, Youngs modulus, Poisson ratio, damage recovery, recrystallization and He-release. Damage ingrowth could be fitted with equations of the type Dp = A(1-exp{-BD}) where p = property, A = change at damage saturation, B = fraction of glass totally damaged by a-decay and D = a-dose.

The main results can be summarized as follows:

Swelling: volume changes at saturation damage were very small (~0.5%)

Leaching: Figure 3 shows that the leach rate does not increase with damage level, it is even indicated to decrease (leaching conditions: static test, demineralized H2O, 14 d, 150C), thus overcompensating the small difference between the glasses without Cm and the ones with Cm for no or very small damage levels. Figure 4 confirms this trend showing results for 4 elements (Si, B, Ca, Mo) of a total of 30 elements analyzed, all confirming the absence of observable damage effects.

Fig. 3

Fig. 4

Mechanical properties: a rather fast decrease in hardness by about 30% with saturation at ~3x1024 a-decays/m3 was observed. At the same time, crack probabilities were significantly reduced and the fracture toughness KIc increased by up to 100%. Youngs modulus decreased also by ~30%. The net result of damage formation was thus reduced brittleness and better resistance against crack formation, i.e. technologically positive effects.

He-release: glasses with 1.5 wt.% Cm-244 which accumulated He as product of the a-decay for about 9 years showed no swelling when annealed for 10 h at 300C. He-release was measured in a Knudsen-cell: between 300 and 420C, release was compatible with thermally activated diffusion of single He-atoms, above 420C and up to 550C, most gas was released with kinetics compatible with gas bubble diffusion. Some He remained in the glass up to ~ 1000C. Note that glass with 7 wt.% Pu-239 would accumulate such a He-level only after ~ 2500 years.

These results cover many of the questions to be answered when vitrifying actinides. One should, however, keep in mind that vitrification does not change the isotopic composition of Pu, and that some further questions have to be answered. The main areas are: while Pu is relatively insoluble

in water, boron is known to show high leaching rates and to become depleted relatively deep in the glasses. B, as a neutron absorber, helps to prevent criticality problems, and should not become depleted. Then, if g-emitters are added to the glass to increase the proliferation resistance, the still open question of the effect of ionizing radiation creating (oxygen) bubbles and the possible consequences on the behavior of the glass should be answered.

Ceramic matrices for direct storage: a large number of ceramic matrices, including SYNROC, which accumulated a-damage due to decay of incorporated Cm-244, have been studied in ITU. Typically, significant swelling (by up to 9%), with the related risk of cracking was found. Also, metamictization (loss of crystallinity and formation of amorphous phases) was often observed at high damage levels (corresponding to 4000 to 10000 years of storage for a 7% Pu-ceramic) with a parallel increase in leach rates. Careful study of damage effects is therefore necessary if additional new ceramics are suggested. Some of the inert matrices discussed above could also be used for solidification and disposal of Pu, e.g. CeO_2, $CePO_4$ and, in particular, zircon ($ZrSiO_4$) because of their good resistance against corrosion in water. For zircon, a good knowledge exists on a-damage effects due to investigations of both old, naturally occurring zircon minerals with a certain content of U and of synthetic zircon with ~ 10 wt.% Pu substituting for Zr (15). Additional work is also needed to define the occupied lattice sites in complex ceramics, the need having been shown for Pu in SYNROC before (16).

SUMMARY

For expeditious dispositioning of Pu, going MOX is a mature and technically proven possibility. Comparatively little R&D in materials science is necessary given the advanced state of fabricating and irradiation MOX fuel in thermal reactors.

The use of inert matrices promises a higher destruction level of Pu. Suitable candidate materials exist and are being tested. More materials research, however, is needed before a final selection can be made, e.g. in the field of radiation damage.

Some of the inert matrices could be used for solidification of Pu, as an alternative to vitrification. A large data base for both glasses and ceramics exists at ITU, and in the literature, to suggest materials and loading levels with Pu. For a fully optimized, tailor-made material some more research is necessary.

ABSTRACT

The overriding objective of U.S. and Russian disarmament initiatives is to dispose of nuclear weapons in such a way that they cannot be reused or reconfigured in the country of origin, or sold to others, for military purposes.

Significant progress has been made in achieving this objective for high enriched uranium from nuclear weapons. Unfortunately, none of the three options now under serious consideration for plutonium disposition, (deep burial, immobilization, or MOX fuel conversion), achieves this objective if implemented in the country of origin. For the MOX option, both the U.S. and Russia, as nuclear weapons states, have the technical and physical resources to extract residual plutonium in the spent fuel via PUREX reprocessing, should future Governments so decide. For the alternative of immobilized plutonium in solid wastes and deeply buried plutonium, the two countries also have both physical and technical resources for later extraction and use of the plutonium.

One approach towards eliminating this potential future threat of reconversion in the country of origin is to implement the MOX Fuel conversion option in a non-weapons state, one with a sufficiently stable political environment to give the world assurance that the plutonium will not be reclaimed for use in nuclear weapons. The Canadian option for utilization of excess weapons plutonium as MOX fuel in CANDU reactors is currently the only option on the table which accomplishes this objective. Atomic Energy of Canada and Ontario Hydro have studied the consumption of up to 100 tonnes of weapons plutonium resulting from projected disarmament programs in Russia and the U.S. by utilizing it as MOX fuel in the Bruce A Reactors, four 825 MWe (gross) CANDU reactors operating on the shores of Lake Huron in the Canadian Province of Ontario. No changes to the reactor designs are required, the fuel is predicted to operate within the existing licensed performance envelope, and the project can begin within four to five years.

Fabrication of the relatively simple CANDU MOX fuel bundles can be accomplished by modifying existing nuclear materials processing facilities in Russia and the United States. Engineering studies of typical U.S. facilities such as the FMEF at Hanford, Washington, and the BNFP in Barnwell, South Carolina, indicate that such facility conversion can be completed, including licensing by the NRC, within a period of 4 to 5 years, and at relatively modest costs. Further studies of other U.S. facilities are underway; engineering studies of existing Russian facilities which could be used for fabricating CANDU MOX fuel have just begun.

Subject to agreement amongst the Governments of Canada, Russian and the United States, the entire program, including storage of plutonium oxide,

fabrication of MOX fuel, transportation, irradiation, and disposal of the spent fuel, would be subjected to independent third party inspection.

CANDU MOX IN BRUCE - THE BASIC TECHNOLOGY

Figure 1 presents the material flow for our reference case, which utilizes the same standard 37 pin fuel bundle design as is currently operating in most CANDU reactors. As indicated in this figure, the burnup of 9,700 MWD/T is slightly higher than the 8,300 MWD/T achieved with natural uranium, thus leading to a slight reduction in spent fuel produced.

Fig. 1

As shown in Fig. 2, the plutonium concentration is about 1.2 % in the outer 18 fuel pins, and about 2% in the next row of 12 fuel pins, with the central 7 pins containing only depleted uranium oxide and dysprosium oxide burnable poison. Preliminary analysis indicates that the thermal performance of this MOX fuel bundle during normal and accident situations will be well within the current AECB licensing envelope at Bruce.

Fig. 2

A multiphase program is planned, including a first phase involving production of up to 50 CANDU MOX bundles for testing at the ZED and NRU facilities at Chalk River. Results will provide confirmation of nuclear, mechanical, and thermal design of the MOX fuel and core design, and would be used to support safety analyses and licensing by the AECB. A second "pilot scale" phase, consuming up to 1 tonne of weapons plutonium, would produce larger quantities of CANDU MOX bundles for irradiation in Bruce. And finally, a program of full MOX production, utilizing up to 2.1 tonnes of U.S. plutonium per year, in two Bruce reactors would begin by 2002. A similar program in the Russian Federation is now being evaluated by a joint Canadian - Russian technical team, with results anticipated by summer, 1996.

An advanced design CANDU fuel bundle, called CANFLEX, is now under development. The design uses 43 fuel pins instead of the 37 pins in the reference design. Commercial validation of the CANFLEX design using natural uranium is expected by around 2000, and if successful, could then be adapted to MOX application via additional fuel qualification efforts. When applied to MOX fuel, CANFLEX would allow higher plutonium loadings and would achieve a burnup of about 15,500 MWD/T, thus permitting an increase in plutonium consumption rate utilizing the same MOX fuel production rate as in the reference case. Figure 3 presents one deployment option which will be considered for this CANFLEX case.

Fig. 3

MOX FUEL SUPPLY IN THE U.S; OPTIONS BEING EVALUATED

Atomic Energy of Canada and Ontario Hydro have been participating in DOE's Material Disposition program, which includes a Programmatic Environmental Impact Statement (PEIS), separate technical and economic evaluations, and a Record of Decision currently scheduled in early Fall, 1996. Because of the unique flexibility of the CANDU design to adapt itself to many different fuel cycles, preliminary conclusions indicate that MOX fuel can be incorporated in the design with no changes to the reactor hardware, and within the current licensing envelope. Because Ontario Hydro's Bruce A Station contains four 825 MWe CANDU reactors, it is capable of utilizing all of the U.S. and Russian plutonium at a single station, thus simplifying the logistics, including transportation, as compared with other options which require multiple sites. For these reasons, we anticipate that DOE's draft Environmental Impact Statement,

to be issued shortly, will select the CANDU option as an option to be evaluated in the final stage of DOE's decision making process.

Atomic Energy of Canada and Ontario Hydro recognized early on that the criteria for final selection will focus on economics, since only those options which meet the safety, technical viability, safeguards and security will have survived the prior screening process. Economics are driven primarily by the incremental cost of MOX fuel.

We concluded that a major cost savings could be realized if an existing U.S. facility could be converted for MOX fuel fabrication purposes. In addition to the obvious cost savings as compared to a greenfield facility, use of an existing facility allows an earlier start to the program, and in some cases has the advantage of an existing base of local support, as compared to potential difficulties of siting a greenfield facility. The facility mission for MOX fuel from weapons plutonium would require as little as 15 years followed by a short Decontamination and Decommissioning period. Therefore, long lifetime structures and components, such as used in European MOX facilities, would not be required. The entire program could thus be treated separately and independently from other, often divisive, issues such as the ultimate disposition of plutonium in civilian spent fuel.

Figure 4 shows the Bruce Reactor site, along with four existing U.S. facilities which are being examined for possible conversion to CANDU MOX facilities: the Fuels Materials Examination Facility (FMEF) at Hanford, Washington, the Barnwell Nuclear Fuel Plant at Barnwell, South Carolina, the P Reactor Fuel Building at Savannah River, South Carolina, and the DAF at the Nevada Test Site.

Fig. 4

Another deployment option being considered is to design the MOX fabrication facilities in the U.S. so they can later be expanded to produce LWR MOX fuel, thus further accelerating the full disposition of U.S. weapons plutonium. The LWR phase would begin after NRC licensing approval of a U.S. utility application for MOX fuel in a commercial LWR.

MOX FUEL SUPPLY IN RUSSIA; OPTIONS BEING EVALUATED

Under the sponsorship of the Canadian Government, Atomic Energy of Canada, Ontario Hydro and Minatom have begun a feasibility study aimed at evaluating the production of CANDU MOX fuel in Russia from excess weapons plutonium, for consumption in the Bruce Reactors. Several exchange visits have already taken place, and the study is due to be completed this summer. The study is similar to the one sponsored by the DOE in 1994. The Russian - Canadian feasibility study has three main elements: 1) MOX Fuel Supply, 2) Safeguards, Security and Transportation; and 3) Economic Evaluations. The economic evaluations, which will permit a comparison of the MOX option with other options being considered in Russia, are obviously critical to a final decision on disposition of Russian plutonium. A key element in this evaluation will be the cost of MOX fuel fabrication, including the cost of facility conversion, and the cost of transportation.

There are three pilot installations in Russia to produce MOX fuel: two at the MAYAK association in Osersk, and one at RIAR in Dmitrovgrad. The current capacity of the "Paket" installation at MAYAK allows production of 10 to 12 breeder sized assemblies per year for use in BN-600/350 reactors. Each assembly contains about 300 KG of MOX fuel containing 20% plutonium. A modified "Packet" installation at MAYAK has a capacity of about 40 breeder fuel assemblies per year (1 tonne of MOX fuel per year).

And the "Granat" installation at RIAR in Dmitrovgrad is about 1 tonne of MOX fuel per year.

In addition to these pilot scale facilities, an industrial scale MOX facility was erected at the "Complex 300" plant at MAYAK, but construction was stopped at about the 50% completion stage, due to lack of near term demand. This facility was to have a capacity of 900 breeder fuel assemblies per year, or about 60 tonnes of MOX fuel per year.

CONCLUSIONS - FIVE REASONS WHY THE U.S. AND RUSSIA SHOULD SELECT THE CANDU OPTION.

In summary, the authors believe it is in the best interests of both the US and Russian Governments to select the Bruce A CANDU reactors for disposition of their excess weapons plutonium for the following reasons:

It is the only option which affords both countries the opportunity to demilitarize their excess plutonium weapons in a third, neutral, non-weapons state.

It affords the international community assurance that this excess weapons plutonium will be under full IAEA safeguards from the moment the plutonium pit is converted to oxide feed material until the fuel is in safe geologic storage.

It can be initiated in a short period of time, less than five years, and can be completed within 15 to 25 years thereafter.

Costs for the disposition program are moderate, as compared to alternatives for plutonium disposition, and especially as compared to the prior costs of military readiness.

It requires only one site for MOX utilization, thus enhancing the safeguards and security and simplifying the transportation logistics, as compared with using multiple sites for plutonium disposition.

DISPOSITION OF EXCESS PLUTONIUM USING "OFF-SPEC" MOX PELLETS AS A SINTERED CERAMIC WASTE FORM

Guy A. Armantrout
Leslie J. Jardine
Lawrence Livermore National Laboratory

ABSTRACT

We describe a potential strategy for the disposition of excess weapons plutonium in a way that minimizes 1) technological risks, 2) implementation costs and completion schedules, and 3) requirements for constructing and operating new or duplicative Pu disposition facilities.

This is accomplished by an optimized combination of 1) using existing nuclear power reactors to "burn" relatively pure excess Pu inventories as mixed oxide (MOX) fuel and 2) using the same MOX fuel fabrication facilities to fabricate contaminated or impure excess Pu inventories into an "off-spec" MOX solid ceramic waste form for geologic disposition. The key to the combination approach is the use of a sintered ceramic waste form (SCWF) consisting of a UO2 encapsulating matrix for the excess PuO2 inventories. The SCWF will have a high probability of being acceptable for geologic disposition because it is similar to an unirradiated MOX fuel matrix without fission products. Because it can be fabricated using the same basic technologies, processing equipment, and facilities used to fabricate the MOX fuel for reactors, there is no need to construct and operate specialized and duplicative facilities using other immobilization technologies such as vitrification.

Diversion protection for the SCWF to meet the "spent fuel standard" introduced by the National Academy of Sciences (1,2) can be achieved in at least three ways. 1) One can utilize the radiation field from defense high-level nuclear waste by first packaging the SCWF pellets in 2- to 4-L cans that are subsequently encapsulated in radioactive glass in the Defense Waste Processing Facility (DWPF) glass canisters (a "can-in-canister" approach). 2) One can add 137Cs (recovered from defense wastes at Hanford and currently stored as CsCl in capsules) to an encapsulating matrix such as cement for the SCWF pellets in a small hot-cell facility and thus fabricate large monolithic forms. 3) The SCWF can be fabricated into reactor fuel-like pellets and placed in tubes similar to fuel assemblies, which can then be mixed in sealed repository containers with irradiated spent nuclear fuel for geologic disposition.

INTRODUCTION

With the end of the cold war, major planning efforts were begun for the management of the excess fissile materials that would result from the reduction of U.S. and Russian nuclear stockpiles.This was motivated by the fear that such a large inventory of weapon-quality fissile material posed a worldwide risk of nuclear terrorism or nuclear proliferation. The United States and Russia are seeking cost-effective methods for the management and ultimate disposition of these materials, with special emphasis on plutonium, that achieve each country's nonproliferation goals and that can be implemented in a timely manner. The current Russian position strongly favors burning the excess Pu in nuclear reactors. The United States is evaluating options that include, but are not limited to, burning excess Pu in existing reactors or immobilization with radionuclides in glass or ceramic matrices; in either case the final product is buried in a geologic repository. Deep-borehole (2-4km) burial of Pu in an immobilized form is also being evaluated. All these options have advantages and drawbacks. This paper outlines a potential strategy for disposition of excess Pu in two streams: burning suitably pure Pu (as MOX) in existing reactors, and disposing of contaminated or impure Pu as a sintered ceramic waste form (SCWF) containing 2-10 wt% PuO2 in a UO2 matrix, similar in form and concentration to either unirradiated or spent MOX fuel. This alternative approach may minimize capital outlays, repository acceptability issues, and implementation duration schedules.

DISPOSITION CRITERIA

Disposition of excess Pu must satisfy three key objectives to achieve overall safety and nonproliferation goals:

1. Rendering the Pu relatively inaccessible for nuclear weapons use

This objective was one of the principal outcomes of the National Academy of Sciences study, (1) which recommended placing the excess Pu in a form that is roughly as inaccessible for weapons use as are the much larger worldwide stockpiles of Pu contained in spent commercial nuclear fuel (SNF). To achieve this degree of inaccessibility requires measures that would make it difficult for a terrorist group, a non-weapons state, or even the United States or Russia themselves to use (or reuse) the Pu in any kind of nuclear explosive device. The National Academy study observed that greater protection than this for excess Pu would be pointless and expensive, and that less protection would be dangerous. This objective is generally interpreted as meeting the "spent fuel standard."

Access to SNF for weapons use is made difficult by the existence of a high radiation-field barrier, by its having Pu isotopic mixtures different than that of weapons-grade Pu, by dilution of the Pu in a ceramic or glass matrix that requires significant chemical and physical processing for recovery, and by containment of the Pu in large, easily accounted and controlled unit item sealed forms. These factors are being considered by the DOE in developing a spent fuel standard to be used in judging the acceptability of any proposed final disposition form before the implementation of any disposition technology approach. (3,4)

2. Conducting disposition operations so that their health and environmental impacts are acceptable

Any processing activity or final disposition material forms that could adversely affect the environment after geologic disposal must meet myriad environmental, health, and safety regulations. Pu processing operations, geologic repository operations, and final disposition forms that could affect worker or public radiation doses or exposures to hazardous chemicals must meet or exceed the regulative requirements.

3. Achieving timely, cost-effective disposition

If a given strategy is to achieve timely, cost-effective disposition of excess Pu, all necessary operations must be technologically viable so that R&D schedule times can be minimized. That viability depends on the existence (or ready construction) of appropriate facilities, equipment, and technologies. Pu disposition options requiring high front-end costs (e.g., for construction of new facilities or processes and for the supporting R&D) will not be regarded as desirable by the current balanced budget-minded Congress. Life-cycle costs (which include operational expenses and decommissioning), which are usually discounted, have less immediate, but still non-negligible, impacts and must also be minimized.

OVERVIEW OF DISPOSITION STRATEGIES

Many disposition strategies were considered in the NAS report, (1) including space launch and sea dilution. Three of these general Pu disposition strategies are under evaluation by the DOE Office of Fissile Materials Disposition (3,4): 1) nuclear burning in a reactor, 2) immobilization with radionuclides in solid matrices to achieve the spent fuel standard, and 3) burial in deep (2-4km) boreholes in ancient rock. The Russians favor nuclear burning as a way of using the energy content of the fissile Pu. Many in the United States, on the other hand, consider the Pu as "waste" to be disposed of by the most expedient and cost-effective method. The draft Preliminary Environmental Impact Statement (3) assumed the use of a single strategy for all excess U.S. Pu inventoriesthat is, for both relatively pure Pu inventories recovered from weapon components and other, less pure Pu in storage or contained in

processing residues or scraps at various U.S. DOE sites. The relative advantages and disadvantages of the three strategies are discussed below.

1. Nuclear Reactor Burning. This approach achieves disposition by burning MOX fuel containing the Pu in a nuclear reactor and then discarding the spent MOX fuel, without reprocessing, in a geologic repository. The major advantages of this approach are its technical maturity (particularly in Europe), its partial favoring by the Russians (who however favor recovery and recycle of the Pu in the spent fuel), and the achievement of the spent fuel standard by the irradiated product form. Both the once-through and recycle approaches reduce the overall weapons Pu inventory and change the plutonium isotopic mixture. The primary disadvantages include possible opposition by opponents of nuclear power, the need to purify impure Pu before MOX fabrication, and reliance on a final geologic repository that is not yet operational. The aqueous technologies used in purification of Pu are expensive and generate significant quantities of secondary low-level and transuranic (TRU) wastes.

2. Immobilization with Radionuclides. This approach achieves the spent fuel standard by incorporating the Pu in a stable, solid matrix containing radionuclides (high-level radioactive defense wastes or 137Cs) whose radiation field, in conjunction with the chemical dilution, large sizes, and safeguards and security, acts as a deterrent to theft or reuse. (5) The immobilized form is eventually discarded in a geological repository in a manner similar to SNF. Immobilization may be a faster, simpler, and cheaper way to achieve the spent fuel standard than reactor burning. The technology is less mature than reactor burning, however, and shares the same concerns over the lack of a geologic repository.

3. Deep Borehole Burial. This approach depends on the depth of the geological isolation, rather than on a radiation "spike" and on physical and chemical characteristics, as in the first two approaches, to achieve the nonproliferation objectives. Its chief advantages are simplicity and perceived permanence, neither of which is offered by the reactor or immobilization approaches until a geologic repository is operated, filled, and sealed. Significant licensing and siting issues must be resolved before implementation, however. (3,4)

DEVELOPMENT OF SINTERED CERAMIC WASTE FORM STRATEGY

None of the three technology approaches just described can alone provide an optimum disposition strategy. We therefore propose a hybrid strategy, not yet evaluated by DOE, that combines the advantages of two of the technologies to achieve cost-effective, timely disposition.

Because both the United States and Russia possess reactors capable of burning excess Pu, we take reactor burning as a main constituent of our hybrid strategy. And because U.S. Pu policy discourages the development of breeder reactor technology, we assume the use of existing thermal reactors in the United States (or possibly Canada). It remains to be ascertained that there is sufficient reactor capacity which can be made available and that this approach is politically and publicly acceptable. Reactor burning alone has the disadvantages already described which includes the need to purify much of the feedstock excess Pu to remove impurities incompatible with reactor fuel specifications. The monetary value of Pu as a reactor fuel in the U. S. is negative, given the current cost of low enriched uranium fuel, so the United States has little incentive to recover impure Pu. We suggest instead that a better approach would be to discard any excess Pu that would require significant purification by fabricating an acceptable geologic repository solid form.

This would reduce the Pu inventories requiring reactor burning and would shorten the completion schedule (by reducing time-consuming reactor operations); it would probably also reduce the number of reactors needed. For this approach to be attractive, however, there must be a low-cost existing technology for discard of the impure Pu not going to the reactor burning option that meets existing environmental laws, anticipated repository requirements, and nonproliferation objectives.

DOE is considering two discard approaches (3,4): deep borehole disposition and immobilization with radionuclides followed by geologic disposition. Deep-borehole disposition would require significant effort to modify existing laws, complete the licensing processes, and characterize a potential site. This preparatory effort would be the same for any borehole disposition strategy, essentially independent of the quantity of Pu to be discarded. New facilities would be required for the borehole operations, increasing up-front costs and possibly introducing implementation time delays. It is unlikely that this approach would be cost- or time-effective for the smaller quantities of impure Pu not destined for burning as MOX in a reactor as part of the proposed hybrid disposition strategy. Thus, deep-borehole disposition does not appear particularly advantageous as part of this strategy.

The immobilization approaches under consideration involve use of a variety of matrix forms for Pu entrainment, including glasses, ceramics, or possibly a glass-bonded zeolite. (3,4) Any waste form intended for repository emplacement must qualify for long-term geological disposal; qualification is a lengthy process and would add to the disposition cost and time for any new waste forms.

Glasses are being developed for disposition of high-level waste from the Defense Waste Processing Facility (DWPF). Since glasses proposed for DWPF high-level waste immobilization were not developed for Pu containment, there are technical problems involving Pu solubility and qualification problems regarding repository acceptability of existing glass waste forms containing high concentrations of fissile materials for Pu disposition. Ceramic or other waste forms under consideration have similar and probably greater concerns.

For a multitude of technical reasons, existing glass immobilization facilities (such as DWPF) cannot be used directly for Pu disposition in glass. In the case of DWPF, for example, criticality considerations would require new melter designs and extensive feed preparation facility modifications and new supporting technology development. Ignoring any issues of delaying the current DWPF mission schedule for HLW vitrification, this would require major front-end investments in research and (eventually) in facility construction and modifications that could exceed the cost and time penalties of simply purifying the impure Pu with current Pu processing technologies for reactor burning.

The acceptability of the Pu disposition waste form within the repository must also be considered. Two waste forms have received significant attention in the United States: DWPF glass and spent commercial nuclear light water reactor (LWR) fuel. DWPF glass, while acceptable for containment of defense high-level waste at the Savannah River Site, is not likely to be directly suitable for Pu containment. This would require the development of alternative glass compositions to serve as the Pu containment systems. Spent LWR fuel is of particular significance in this context, because U.S. policy contemplates direct disposal of such fuel in a geological repository, without reprocessing. In this case, the primary

barriers to Pu release to the geologic environment are the containers, any other engineered barriers used to emplace the spent fuel in the repository, the spent fuel assembly structural materials, and the ceramic UO_2 matrix form encapsulating the PuO_2 and fission products in the spent fuel.

To achieve waste form acceptability for the repository, to avoid new facility construction or new process development, and to control costs and schedule, we suggest a hybrid strategy that produces only one type of material form. The proposed waste form is a UO_2/PuO_2 matrix containing 2-10 wt% PuO_2. Such a matrix is prepared and sintered similar to MOX reactor fuel fabrication and has a chemistry and morphology similar to MOX reactor fuel. Figure 1 shows the proposed strategy, here specifying a light water reactor (LWR) to burn the relatively pure Pu in MOX fuel and using the MOX fabrication technology to fabricate and discard the impure Pu as a sintered ceramic waste form (SCWF). The primary advantages of such a waste form include likely repository acceptability with minimal additional qualification testing for the SCWF and compatibility of SCWF processing and facility requirements with those routinely used in Europe for MOX fuel fabrication. If a permanent discard solution other than a geologic repository for the spent LWR nuclear fuel must be found, that solution would also apply to the discard SCWF waste form proposed here. Disposition of 10 to 20t of impure Pu in any of the SCWF forms suggested would result in a MOX fuel-like component of repository waste that is less than 1% of the projected U.S. SNF inventory (about 80,000t).

Fig. 1

The first step in fabricating such a compatible waste form for the impure Pu would be to make a compressed PuO_2/UO_2 mixture and pellet similar to the starting form for MOX fuel, as indicated in Fig. 1, but without the dimensional tolerances and feed Pu purity requirements applicable to MOX destined for a LWR. Impurities introduced with the impure Pu feed would in most cases probably be contained in the waste form and would likely not decrease repository acceptability any more than the fission products normally contained in spent LWR fuel. Such a compressed pellet form would then be sintered in a reducing atmosphere to increase grain size and intergranular bonding to form a sintered matrix, which would constitute the final Pu containment waste form. This sintered ceramic waste form (SCWF) pellet would then be encapsulated in one of two types of container, as suggested in Fig. 1: 1) relatively small (2 to 4L) cans, which would then be sealed and installed in the glass can-in-canister configuration for addition of a radiation barrier such as DWPF glass containing defense HLW, or 2) relatively large DWPF type canisters (0.6m o.d. - 3m long), to which would be added an encapsulating grout matrix containing ^{137}Cs. A third, hypothetical approach could be to fabricate canisters of SCWF pellets in geometries like fuel assemblies and mix these canisters with irradiated SNF in the multipurpose canister (MPC)-like repository container (6) for final emplacement. Radiation fields calculated for mixing five fuel-like SCWF assemblies with 12 SNF assemblies from pressurized water reactors (PWRs) are on the order of 300 rem/hr at 1m from the centerline 30yr after MPC container loading; this is similar to the radiation fields for the PWR spent fuel assemblies alone.(5) Such fuel-like SCWF assemblies would require a level of protection similar to MOX assemblies until they were mixed with the spent fuel, at which time the essence of the spent fuel standard would be achieved.

Clearly, such an approach has the advantage that the SCWF waste form would be produced with the same technology used for MOX reactor fuel production. If integration of the private and government sectors can be accomplished, it may be possible to utilize the same facilities for both processes, as indicated in Fig. 1. If such integration of the MOX fuel and SCWF fabrication is not economically or politically feasible, duplication of the MOX fuel fabrication technology in the Pu recovery facility for SCWF fabrication would very likely be faster and cheaper than development of a new immobilization technology and processing capability.

FEASIBILITY OF THE SINTERED CERAMIC WASTE FORM (SCWF) IMPLEMENTATION

The feasibility of the approach shown in Fig. 1 was assessed by assuming that the 50t of projected excess Pu feed material consists of 40t of relatively pure Pu suitable for reactor burning and 10t of impure Pu to be discarded in the SCWF. The number of reactors required to burn 40t of relatively clean Pu would depend on the reactor types selected and on the MOX Pu loadings, but should be within the range of available existing reactors. The 10t of impure Pu would be blended and sintered with depleted UO2 to form the SCWF pelletsessentially, "off-spec" unirradiated MOX pellets.

Figure 2 indicates the number of DWPF cans that would be required to hold the 2- to 4-L SCWF cans in the DWPF can-in-canister option, as a function of average Pu loading in the SCWF matrix. Since 5000 to 6000 DWPF canisters are projected for completion of the defense high-level waste immobilization mission, discard of the impure Pu within these canisters, with only a modest increase in the total of DWPF canisters, using the can-in-canister approach is possible with average Pu loadings of 0.5 wt% or higher in the SCWF. This loading is substantially lower than that in new MOX fuel and is comparable to that in normal spent LWR fuel. Higher Pu loadings (up to 5wt%) would substantially reduce the number of 2- to 4-L cans that would have to be handled in the can-in-canister option and would reduce the disposition cost. Plutonium loadings of a few weight per cent should not have a significant repository impact as compared with SNF assemblies from the standpoint of criticality concerns, particularly during the post-closure period. In fact, the use of depleted UO2 as a matrix material virtually eliminates long-term criticality concerns as the 239Pu decays to 235U. If the 239Pu were contained in a non-uranium matrix, the possibility may occur for 235U geological reconcentration as a result of long-term migration and waste form degradation; this could not occur after the 239Pu decays with the use of a depleted UO2 matrix.

Fig. 2

Figure 2 also indicates the number of containers similar to the proposed multipurpose containers (MPCs) (6) that would be required to discard 10t of impure Pu if the SCWF pellet products are mixed with a 137Cs-loaded grout in a DWPF-like container or fabricated as canisters looking like MOX fuel assemblies and loaded five at a time into an MPC-like unit. No more than a few hundred MPC-like containers would be required for Pu loadings of a few weight per cent. This is consistent with the normal Pu loadings in both spent MOX fuel and normal SNF. Even at loadings as low as 0.5wt%, fewer than 1000 MPC-like containers would be required.

CONCLUSIONS

Using the hybrid strategy of existing thermal reactors to burn clean excess Pu and fabricating a sintered ceramic waste form (SCWF), largely

of depleted UO2, for discard of impure excess Pu has the following advantages:

1. The SCWF mimics the chemical and morphological forms of unirradiated MOX LWR fuel and should have similar repository impacts over geological times. The SCWF should be as acceptable for repository disposal as spent MOX LWR fuel, or even spent commercial low enriched uranium LWR fuel.
2. The proposed SCWF pellet fabrication for impure Pu utilizes facilities and technologies virtually identical to those routinely used in Europe to fabricate mixed oxide (MOX) fuel, thus minimizing new required facilities or new technology development and demonstrations.
3. The proposed use of SCWF pellets to dispose of impure excess Pu eliminates the need to purify it, as would be required in any MOX reactor-based disposition strategy.
4. The SCWF provides a direct avenue for disposition of TRU scraps of impure Pu generated during the recovery of Pu from excess pits and for residues from MOX fuel fabrication. This avoids the need for additional processing facilities or operations for recovery and minimizes disposal of these Pu-containing residues.
5. Radiation barriers and the achievement of the spent fuel standard can be readily implemented by 1) using the can-in-canister approach with DWPF as the source of a glass containing a high-level waste radiation barrier, 2) encapsulating the SCWF pellets in a grout matrix containing 137Cs in a DWPF type can in a small hot-cell facility, or 3) by mixing the SCWF pellets, packaged as a fuel-like assembly (or similar size container), with SNF from normal power reactor operations.
6. Use of a single waste form and fabrication process similar to unirradiated MOX for impure excess Pu and for MOX fabrication of the pure Pu for burning in existing reactors would reduce up-front costs for capital construction, research, development, and demonstration.
7. Because existing reactor capacity in the United States (or possibly Canada) would be utilized, and because no new technology development is required, this strategy would minimize the time required to achieve the spent fuel standard for excess Pu.
8. Adoption of the reactor burning approach may assist in developing effective linkages with reactor disposition approaches for pure excess Pu currently favored by the Russians.
9. MOX fuel fabrication and reactor burning can be time phased with the production of the SCWF fabrication to best utilize facility capacity and to optimize schedules. Multiple-line MOX plants could be considered for simultaneous processing and fabrication of pure and impure excess Pu forms.

CONTRIBUTIONS OF THE COMMERCIAL FUEL CYCLE INDUSTRY TO THE US WEAPONS PLUTONIUM DISPOSITION PROGRAM

Marilyn F. Meigs
BNFL Inc.
Program Manager
Fuel Cycle and Materials Processing

ABSTRACT

The manufacture and burning of Mixed Oxide (MOX) fuel is a technically mature industry in Europe, having developed as a natural progression of the closed fuel cycle infrastructure in the United Kingdom, France and elsewhere in Europe. This paper discusses the relevance of the European MOX fuel experience to the US excess weapons plutonium program, identifies unresolved technical issues, and presents a step-wise progression towards utilization of MOX fuel in North American reactors, utilizing the capabilities and expertise of the European commercial fuel cycle industry.

BACKGROUND

The end of the Cold War has dramatically altered the course of the Department of Energy (DOE) from one of nuclear materials production to that of nuclear materials disposition. The National Academy of Sciences has conducted detailed studies on the preferred approaches to the disposition of excess weapons plutonium and concluded that concurrent programs on (1) reactor use as Mixed Oxide (MOX) fuel and (2) immobilization in vitrified High-Level Waste (HLW) were worthy of pursuit as the best, most timely approaches to plutonium disposition.

The DOE Office of Fissile Materials Disposition is studying these two options, among others, as the subject of a Programmatic Environmental Impact Statement (PEIS), which will serve as the vehicle for narrowing the options down to one or more finalists, expected to be announced in the fall of 1996.

Meanwhile, DOE has enlisted the help of its laboratories, as well as the private sector, in determining the path forward for deployment of a MOX use program, should the decision be made to proceed in this direction. The DOE program for MOX use assumes that consumption rate can be maximized by using full-core loads. This will necessitate the introduction of burnable poisons in the fuel to control reactivity (in contrast, the commercial MOX fuel experience is based on partial core loadings of MOX fuel without any added burnable poisons).

Lawrence Livermore and Los Alamos Labs are developing non-aqueous chemical processes to convert the plutonium metal "pits" to an oxide form suitable as feed material for a MOX plant; Los Alamos is the "lead lab" for MOX fuel manufacturing facilities and technology; and Oak Ridge is

the "lead lab" for MOX use in North American reactors. These laboratories are reaching out to the commercial fuel cycle industry for advice, experience, and expertise to insure that a MOX program, if chosen, will succeed. Additionally, Oak Ridge and DOE-Headquarters are in continual dialogue with utilities, reactor vendors, and fuel vendors to determine the nature and extent of domestic interest in a MOX use program in North America.

EUROPEAN MOX EXPERIENCE

While it is fair to acknowledge that the US once had a MOX fuel cycle program underway (including six reactors that burned MOX fuel in the U.S.), it is likewise fair to say that the program experienced a premature death in the 1970's when reprocessing, and therefore MOX use, was abandoned in the US as a matter of policy. Meanwhile, the European program continued to evolve to the point that, today, that experience provides a wealth of knowledge directly applicable to the US program - - and, for that matter, the Former Soviet Union program - - to dispose of their excess weapons plutonium inventories.

MOX Fuel Production and Irradiation

Belgonucleaire, Siemens, Cogema, and BNFL have provided MOX fuel as far back as 1963 for irradiation in research reactors and commercial nuclear power plants in Switzerland, Germany, France, Italy, Belgium and Japan. Belgonucleaire and Siemens pioneered the MOX manufacturing business, having produced over 1000 MOX fuel assemblies over the last three decades in their respective facilities sized at 30-35 tons/yr production capacity. Cogema and BNFL will soon eclipse the Belgonucleaire and Siemens production capabilities with their respective, large-scale plants (120MT/yr each) that are presently either under construction or coming on-line to provide MOX fuel to their customers worldwide.

While specific fuel performance data on MOX fuel is generally not available in the open literature, in general, the performance has been excellent, with burnups reaching as high as 30-40 GWD/MT, and good response to reactor transients. No data is available on severe fuel damage behavior, but there is little indication that this would much different than the behavior of urania fuel.

MOX Fuel Manufacturing Technology

The basic technology for manufacture of MOX fuel involves co-milling of the uranium and plutonium oxides to obtain a homogeneous mixture, pellet pressing (with or without binders), pellet sintering, pellet finishing, and loading of the pellets into pins for fuel assembly.

Recent advancements in the MOX manufacturing process have resulted in streamlined production and improved MOX fuel performance. The French and Belgians have developed a process called MIMAS (Micronized Master Blend) in which a "master blend" mixture of 20-30% plutonium is premilled (micronized) and then blended with uranium oxide to form the final mixture (nominally 4-6% Pu). Use of this "master blend" significantly reduces the milling time required in the process. A similar process called "Optimized Co-Milling" (OCOM) has been developed by Siemens. BNFL's advanced process is referred to as the "Short Binderless Route" (SBR), which utilizes a high-energy Attritor Mill to blend the uranium oxide and plutonium oxide feed materials
within a relatively short cycle time, to achieve extremely good homogeneity. Following the mixing step, the powder is agglomerated in a spheroidiser which allows the mixture to flow freely to the pelleting press.

All the advanced MOX fuel manufacturing processes offer significant improvements over traditional co-milling in terms of fuel homogeneity, fission gas retention, and high burn-up.

THE POTENTIAL FOR DISPOSING OF US WEAPONS PLUTONIUM AS MOX

The Technical "Show-Stoppers"

Assuming MOX is chosen as a disposal route for US excess weapons plutonium, there are several technical uncertainties that have been identified by the various technical experts involved in the program. None of these technical uncertainties are true "show stoppers"; nevertheless, some demonstration work will be required to deal with these issues, which are summarized as follows:

1. Acceptability of the feed PuO_2 material for use in a commercial MOX fabrication process. LLNL and LASL, who are developing the pit conversion processes, will need to interface with the commercial MOX fuel fabricators to determine the suitability of their feed material in terms of morphology and other specifications.
2. Presence and behavior of gallium. Gallium is used as an alloying agent in the manufacture of plutonium pits. Studies need to be conducted to determine the behavior of the gallium during the pit conversion process and then during the pellet sintering process. If the gallium escapes during either of these processes (as is expected based on preliminary findings), then this needs to be taken into consideration in terms of the impact on the processing design and performance. If the gallium remains in the MOX pellets, then a determination needs to be made as to its effect on fuel performance.
3. Use of burnable poisons. At core loadings above 50% MOX fuel, the excess reactivity of the core needs to be controlled by the introduction of burnable poisons (gadolinium, erbium, dysprosium, ZrB_2, etc.). Since the US MOX program assumes 100% core loadings to maximize plutonium consumption, burnable poisons will need to be incorporated into the fuel design. No data exists on MOX doped with burnable poisons, though there is some experience with the use of burnable poisons in urania fuel which may be directly applicable. Further demonstration work on the fabrication and irradiation of MOX fuel with burnable poisons is thus a prerequisite for licensing of the fuel.
4. Applicability of the existing database (from European MOX fuel experience) to the US program. There are of course differences in the isotopic mix of weapons-grade plutonium as compared to commercial-grade plutonium. These differences stem from the higher proportion of the heavier isotopes of plutonium present in the commercial-grade material, which results in higher radiation exposure. Dose to operators from commercial-grade plutonium has been controlled in the design of the plants that utilize commercial-grade material (remote handling and additional shielding). Thus, existing experience in handling "dirtier", commercial-grade plutonium represents the "worst case" envelope within which the "cleaner", weapons-grade material will fall. No surprises are expected in dealing with the purer, weapons-grade material. The major difference will be in the criticality design aspects of the MOX fuel manufacturing plant, which are easily accommodated.

Jump-Starting the US Program for MOX Utilization

A driver in the US Excess Weapons Plutonium Disposition Program will be the rate at which progress is made in disposing of this material. Thus, a program that is cluttered with endless R&D and hampered by licensing uncertainties is Dead-On-Arrival. For this program to actually succeed,

early demonstration and rapid deployment are the keys to economic, technical, and programmatic success.

Thus, the program should be designed to begin with near-term steps that can be achieved with technical certainty, while other unknowns are gradually and systematically addressed for full deployment of the program. Such a step-wise program could be jump-started by utilizing existing facilities, expertise, and experience base within the European MOX community. One example of such a step-wise program is given below, though other permutations are certainly possible.

Step 1: Fabricate MOX fuel pellets utilizing pure and Gallium-contaminated plutonium feed material from the US Excess Weapons Plutonium inventory. Pellet fabrication could be undertaken at a number of existing MOX fabrication "demonstration" labs in Europe, such as the BNFL MOX Demonstration Facility at Sellafield.

The importance of using commercial fabrication technologies cannot be overemphasized. Any pellet fabrication tests that do NOT use commercial technology are worthless in the eyes of the NRC for licensing purposes and would have to be repeated. The information gained from these simple pellet fabrication tests would demonstrate (a) the acceptability of the oxide feed material for the pellet fabrication process, and (b) the behavior of the gallium during the pellet manufacturing process. These tests could be performed during 1996, i.e., pre-Record-of-Decision (ROD) on the Programmatic Environmental Impact Statement, thereby advancing the program by an entire year compared to waiting until post-ROD.

Step 2: Manufacture MOX Demonstration Assemblies (MDA's), four assemblies per reactor, for irradiation in candidate North American reactors selected for MOX use. These MDA's can be manufactured at existing demonstration-scale facilities in Europe, thereby utilizing known, commercial manufacturing processes. For BNFL, capacity could be made available for such use at BNF's Sellafield site before the turn of the century. For simplicity, these MDA's would not contain burnable poisons, so as not to complicate the NRC licensing and certification processes. Once approved, core loads of 20-50% MOX could proceed immediately, and meanwhile, test pin irradiations and MDA's for full-core loads of MOX containing burnable poisons could proceed on a separate and slower track. If, for whatever reason, the burnable poisons present unsurmountable certification and licensing problems, then at least the program can proceed using the partial core loads of MOX without poisons. Burn rate can be achieved by utilizing more reactors in the disposition program.

It is assumed here that existing data from European test reactor irradiation trials of commercial MOX will suffice for these early US MDA's and that no separate irradiation trials of MOX derived from this weapons plutonium material will be required.

Step 3: Begin full-scale production of MOX assemblies utilizing any available excess production capacity in Europe while a new plant is designed and constructed on US soil. Utilizing available excess capacity in Europe will bridge the gap between initiation

of a new, US-based MOX plant project and the completion and licensing of that project, which could take as long as 8 years. Utilizing available European production capacity dictates that any US fuel manufactured would be poison-free, so as not to contaminate the otherwise "clean" European facilities. Likewise, utilizing this available excess capacity might mean that the gallium would have to be removed as well, depending on the effect that gallium would have on the operation of these facilities.

Transportation aspects of the European option would have to be taken into consideration. Based on US and European experience in moving both plutonium and MOX fuel, this should not be an unsurmountable obstacle to the use of European facilities in the early stages of the US MOX program.

Step 4: A full-scale US program on MOX utilization would be carried out as dictated by the results of the earlier steps.

ASSISTING THE RUSSIAN PLUTONIUM DISPOSITION PROGRAM

European fuel fabricators are actively involved in providing technical assistance to the Former Soviet Union for the timely disposition of their inventory of excess weapons plutonium. In addition, the European fuel fabricators have been in dialogue their governments to develop multi-lateral mechanisms to assist the Former Soviet Union in implementation of an appropriate plutonium disposition strategy.

Political Will and Political Winds

The single most threatening show stopper to this program, in BNFL's opinion, is the US political will and stamina to get on with the program! DOE's track record for completing any large undertaking over the last 20 years is miserable at best. Yet it is heartening to observe in this instance a keen desire on the part of the DOE labs and the DOE headquarters program managers to go beyond the "Plutonium Disposition" study phase into an action-oriented phase involving the capabilities of the private sector.

Political winds tend to shift every election cycle, providing little assurance of continuity of any long-term commitments to a long-term plutonium disposition program. Thus, the best means of eliminating the political uncertainty is to place the MOX program firmly in the hands of the private sector as much and as soon as possible.

A report prepared by Oak Ridge National Laboratory that surveyed world-wide MOX experience emphasizes the significance of the European knowledge base that will enable the US to leapfrog over an expensive and time-consuming R&D phase and go directly to a demonstration and implementation phase. Hopefully, the ability to leapfrog ahead into a commercially driven program will be just the driving force that is needed to overcome the potentially detrimental effects that politics would otherwise play in this important program.

CONCLUSIONS

A proven, mature MOX industry exists to assist the US in the disposition of excess weapons plutonium. That industry is alive and well in Europe, and willing to provide expertise and capabilities to facilitate early deployment of a US MOX program.

ABSTRACT
The primary responsibility of the Environmental Management program is to address the most immediate, urgent risks to human health and the environment from the nuclear weapons complex, while managing long-term contamination and safety threats. Environmental Management cannot meet this responsibility unless it integrates the best risk management practices into its decision making processes. In response to direction and guidance from Congress, the National Academy of Sciences, and other organizations, the Environmental Management program has implemented a risk-based approach to decision making, successfully using a qualitative evaluation process to inform decisions in the fiscal year 1996 and 1997 budget cycles. Risk information will be used even more rigorously and more in-depth for the fiscal year 1998 budget development cycle and beyond. The process of using risk information to establish priorities will improve as the Department improves data quality, incorporates peer review, defines the future of its sites, and keeps its stakeholders fully informed and involved.

INTRODUCTION

In the United States, the nuclear arms race resulted in the development of a vast research, production, and testing network that became known as the "nuclear weapons complex." The complex consisted of 2.3 million acres of land and 120 million square feet of buildings and ranged in diversity from a vast tract of land in the deserts of Nevada to warehouses in downtown New York City that once stored uranium.

The Department of Energy created the Office of Environmental Management in 1989 to manage the legacy of fifty years of nuclear weapon production and research at 137 sites in more than thirty states and territories. The Environmental Management program's responsibility is to address the most immediate, urgent risks to human health and the environment, while managing long-term contamination and safety threats. The program also manages wastes currently being produced during nuclear energy research and development, basic science research, and ongoing missions.

The Environmental Management program is currently facing a decreasing budget while still having to deal with competing requirements and risks to workers, public, and environment. The Department recognizes that credible risk assessment and the best risk management tools are needed to meet its primary mission of protecting human health and the environment. The decisions involved in managing these problems include long-term environmental and public safety concerns, national security issues such as nuclear proliferation, and federal budget limitations. The future course of the Environmental Management program will depend on several fundamental technical and policy choices, many of which we have not yet made.

THE CHALLENGES OF USING A RISK-BASED DECISION MAKING PROCESS

Many concerns have been raised regarding risk assessment: our ability to define what the risks are on a site-by-site basis and in a systematic way; the fact that it matters "who" performs the risk assessments; and the many methodology issues about identifying and assessing risks as well as uncertainty, data gaps, and concerns over the quality of information. Knowing these controversies surrounding risk and the use a risk-based approach for environmental management, two years ago the Department asked the National Academy of Sciences to decide whether and how risk and risk-based decisions could be incorporated into the Environmental Management program. The study resulted in the January 1994 report Building Consensus through Risk Assessment and Management of the Department of Energy's Environmental Remediation Program. In the report, the Academy identified the major obstacles, issues and barriers to implementing a risk-based management approach. The report concluded that the use of risk-based approach could help compare outcomes, build consensus, and gain early public involvement to include cultural, socioeconomic, historical, and religious values, if its purposes and limitations are well-defined.

The Academy also noted that to be effective and useful, the procedures and institutions adopted for risk assessment satisfy several objectives:

They must be credible to stakeholders and the general public.

They must operate expeditiously without threatening scientific validity.

They should consider the full range of risks of concern to the stakeholders in the light of social, religious, historical and political values, future land uses, and cultural values and needs.

They should be efficient and cost effective and produce results that contribute to identification of remedies and priorities that are themselves efficient and cost effective.

Based on the findings of the report from the National Academy of Sciences, that risk-based decision-making was both feasible and desirable for the Environmental Management program, the Department of Energy adopted a set of principles for using risk analysis. The principles (developed by an interagency working group) are designed to be a first cut at defining risk analysis, its purposes, and the principles to be followed by the Department of Energy if it is to be done well and credibly. These principles include four major categories:

Risk Assessment. Use the best available information from all sources; all judgements and assumptions should be explicitly stated.

Risk Management. Analyze the distribution of risk and costs/benefit of potential risk management strategies, using the best available tools and techniques.

Risk Communication. State risk management goals, assumptions, uncertainties and comparisons clearly, accurately, and meaningfully; provide public access in a timely manner.

Priority-Setting. Compare risks by grouping them into broad categories of concern (e.g., high, medium, low) and identifying the population at risk; include as broad a range of views as possible, ideally with consensus.

"THE FIRST STEP" TO LINKING RISK WITH THE BUDGET

Since its formation six years ago, the Environmental Management Program has been beset by public and Congressional concerns over priorities and the pace of cleanup versus total program costs. The Department of Energy's Office of Environmental Management's overall budget grew from approximately $2.3 billion in 1990 to approximately $6.5 billion in 1994. Concerned about this rapid budget increase, yet sensitive to the public concerns about the risks posed by the department's sites, the Congress urged the Department to begin to develop a risk-based approach for sequencing or prioritizing its activities. Specifically, the Conference Report of the Energy and Water Development Appropriations Subcommittee for Fiscal Year 1994, said that the Department "...needs to develop a mechanism for establishing priorities among competing cleanup requirements." Furthermore, the Department was directed to "submit by June 30, 1995 a report...evaluating the risk to public health and safety posed by the conditions at weapons complex facilities that are addressed by compliance agreement requirements." The committee emphasized that it did "not intend [for] the Department to perform an exhaustive formal risk assessment, as that term is frequently used, of the thousands of cleanup activities required by compliance agreements. Instead, the Department [was] directed to estimate the risk addressed by cleanup requirements on the basis of the best scientific evidence available."

In response to the Congressional request, the Department initiated a major effort to define its risks on a site-by-site basis systematically. In reevaluating the Environmental Management program in 1994, the Department announced its intent to establish more credible and consistent methods of conducting risk assessments at its sites and facilities.

In the current climate of decreasing budgets, the public is especially concerned about ensuring that funds are being spent wisely and cost effectively. There are demands to achieve the highest level of risk reduction possible for every taxpayer dollar spent. This can only be achieved by fully understanding all the risks that the program must address, understanding the costs associated with addressing those risks, and making decisions based upon that comprehensive understanding.

Information about risks is generally collected and analyzed at a specific facility or site, or for a particular contaminant or hazard. Such information has not been available for decision making, or for establishing priorities. Many risk-related reports are completed based on requirements specific to a regulation or a compliance agreement and do not allow for comparisons of risks, or for an integrated complex-wide analysis of risk. A primary objective of the draft report entitled Risks and the Risk Debate: Searching for Common Ground "The First Step" (from now on called the "Draft Risk Report"), submitted to Congress in June 1995, was to develop a process that provides an integrated approach to evaluating the risks to human health, worker safety, and the environment posed by conditions at the Department's sites and facilities, and links those risks to compliance requirements and the budget.

The Environmental Management program's Office of Integrated Risk Management adopted a qualitative evaluation matrix for the Draft Risk Report. The process was not designed to replace existing site-specific approaches, but to increase the understanding of all Environmental Management activities, particularly as related to risks to public health, worker health, the environment, compliance requirements, and budget allocations across the EM programs. Department of Energy Field program managers with expertise about these activities at their site categorized the activities in six areas. The intent of the qualitative approach was to describe all Environmental Management activities to develop a consistent, Environmental Management-wide framework for capturing and communicating the information from all Environmental Management sites and facilities.

CURRENT STATUS

The Draft Risk Report to Congress provides the first link between budget, compliance requirements, and risk reduction/pollution prevention activities. The process used for the report provides an initial framework to capture the spectrum of risks (public, health, worker, and environment) associated with planned Environmental Management activities and to link these risks to compliance requirements and the budget qualitatively.

The information provided a baseline from which both DOE and its stakeholders can use to engage in dialogue about the risks and costs associated with the various Environmental Management activities at each site. This baseline information was successfully used in the fiscal year 1996 and 1997 budget processes, as one tool in the decision making process that determined how Environmental Management would allocate its funding, establish priorities, and sequence its work.

The Environmental Management Advisory Board, an advisory group charted under the Federal Advisory Committee Act, was asked to review the Draft Risk Report and the qualitative evaluation process used to develop information linking risk, compliance, and budget for all Environmental Management activities. The Board recognized the process used to develop the Draft Risk Report as an important first step in linking both compliance and budget information. They endorsed the use of the process and endorsed the recommendations made to improve the data quality and assure consistent application and interpretation of those data. Their recommendations to the Department were to:

Improve Data Credibility and Quality by clearly identifying and communicating the assumptions, implementing public and peer review, and using corporate training and workshops. In addition, the categorization of activities needs to be consistent across sites, clear, recognizable and meaningful.

Implement a "three-tiered approach" to improve the risk assessment/management process further, in developing guidance, in conducting qualitative evaluations, and in evaluating the results and process.

Improve stakeholder involvement through a variety of creative approaches to engage stakeholders in the qualitative evaluation process meaningfully. Better information and communication tools are needed for this complex subject if the program is to be effective. Future land use and land use assumptions are critical components of this process, and each site needs specific future land use criteria.

Pay close attention to "timing" issues. For example, a low risk activity can result in much higher risk later if wastes are unstable or leaking. In addition, effects can occur due to the performance of an activity, and should be considered in the decision making process.

Fully integrate the entire process with the budget, long-term cost projections, future land use planning, and stakeholder involvement.

As Environmental Management goes forward to use this process and framework in the fiscal year 1998 budget and planning process, it is carrying out these recommendations. The information provided within the process will change as policy decisions such as land use options are determined for each site, as new regulations and compliance agreements are made, as risk information improves, and as more data become available. The Department believes that having this framework consistently implemented and understood will take more than one year, but that the lessons learned each year will be incorporated into the framework. The Department will continue to work on enhancing risk evaluation methods throughout the year. To enhance a consistent approach that captures the spectrum of risks associated with Environmental Management's programs across the weapons complex, Headquarters has been working with the Field Offices to develop detailed guidance for use in developing the fiscal year 1998 Environmental Management budget. Personnel representing all EM sites and programs and external peer review experts from outside the Department of Energy will conduct evaluations of risk data and process quality at the EM-wide level to improve the risk assessment/management process. Peer review will be accomplished through the following "three tiered approach":

The first tier consists of a central group of experts, stakeholders and regulators to develop the guidance for the comparative risk assessment process. (Complete for the Fiscal Year 1998 budget process.)

The second tier consists of risk assessment professionals, environmental experts, former Department of Energy employees, and Department of Energy field office representatives to conduct the comparative risk assessment. This method will ensure cross-site input, thereby reducing bias, promoting consistency and building credibility for the process. This review will take place on a local and national level. The local review processes will be defined and managed by Field Offices and will take place in the November to April time frame. The national review process will be coordinated by Headquarters budget and risk organizations and is taking place in the January to May 1996 time frame.

The third tier will consist of a group to evaluate the process. This group will consist of some of those in the first and second tiers, and other independent experts. The review group will be responsible for reviewing the process and providing guidance on carrying it out. This group will perform its review in the April through July 1996 period.

In addition to peer review, the Department recognizes that stakeholder involvement is important to both the quality of information and the credibility and validity of the decision making process. The Environmental Management program is using a variety of creative approaches to engage stakeholders in the risk and budget issues meaningfully so that stakeholders have access to accurate, understandable, and timely information. The goal of these activities is to allow stakeholders sufficient time to be able to assimilate the information and an opportunity to be heard during the decision making process.

In collecting information to inform its decision making processes, the Department has begun to account for the various attitudes, interests, and community activities that could be affected or disrupted by performing or not performing an activity. The Department will collect information regarding the potentially negative social, cultural, and economic impacts of activities and the environmental situations they address (e.g., temporary or permanent cessation of important community activities, disruption of traditions or ceremonies practiced by specific populations or groups). Such information will be considered with the other information used to inform priority setting.

Improved stakeholder involvement is dependent on the ability of the Environmental Management program to communicate risk information effectively and to identify meaningful and timely opportunities for public participation. It is vital that EM be clear about the nature of opportunities for public input on environmental decision-making, and be clear about how the public input will be used. For example, the Department is helping stakeholders to participate in the 1998 budget process by preparing a guide entitled Public Participation in the Fiscal Year 1998 Office of Environmental Management Budget. This document identifies the decisions to be made, the key documents being provided to decision-makers, and the opportunities for stakeholder involvement.

Assumptions regarding the future use of land at the Department's sites directly affect estimates of risks to the public, to workers, and to the environment. To conduct meaningful risk assessments and select appropriate remedial methods, sites must first define future land uses with significant public input. To date, several sites have already formulated stakeholder-preferred land uses as a result of the Secretary's initiative to develop site land use plans; these land use assumptions will serve as a basic input into site risk assessments.

Additionally, Environmental Management is supporting several cooperative agreements with independent institutions to work together helping the Department further define and implement approaches to credible risk assessment and risk management practices. These include: development of comprehensive, innovative methods to assess and communicate ecological and human health risks; research programs to foster a greater understanding of the ecological and human health effects associated with remediation activities at specific sites; and development of information for ecological risk analysis. Specific activities will include: working with Field elements and their local stakeholders to improve risk communication between these groups; providing peer review and analysis of Field generated risk information; involving public participation in risk evaluation; and developing tools for communicating risks to nontechnical audiences.

CONCLUSIONS

As the Office of Environmental Management attempts to accomplish its primary mission, protecting human health and the environment, while facing a decreasing budget and competing regulatory and stakeholder requirements, it is developing and using a framework that builds on all of the risk information collected on a site and facility basis and allows for a consistent approach to evaluating risks throughout the nuclear weapons complex.

Clearly identifying and communicating the assumptions used in developing evaluation data will improve the credibility and quality of the data, as will implementing public and peer review and using training and workshops

across the Environmental Management program. Across sites, categorization of activities will be made consistent, clear, recognizable, and meaningful.

The "three-tiered approach" to peer review being implemented will improve risk assessment and risk management processes in: developing guidance, conducting qualitative evaluations, and evaluating the results and process.

Values of stakeholders, including Native Americans and other groups must be considered and solicited actively, meaningfully, and effectively. Sites should clearly explain the basis for their land use assumptions, particularly to identify the degree to which area citizens, tribal governments, regulatory agencies, and other interested parties accept these assumptions. Cleanup decisions must be tailored to accomplish the future land use plans.

Environmental Management successfully used a qualitative evaluation process to inform decisions in the fiscal year 1996 and 1997 budget cycles. Risk information will be used even more rigorously and more in-depth for the fiscal year 1998 budget development cycle and beyond. The process of informing priorities with risk information will improve as the Department improves data quality, incorporates peer review, defines the future of its sites, and keeps its stakeholders fully informed and involved.

IMPROVING REGULATION OF USDOE NUCLEAR SAFETY

Thomas Isaacs*

Steven Crockett

Federal Advisory Committee on External Regulation of DOE Nuclear Safety

ABSTRACT

The Federal Advisory Committee on External Regulation of U.S. Department of Energy Nuclear Safety recently issued its Final Report, in which it unanimously recommended full external regulation of facility safety, worker protection, and environmental protection of essentially all DOE nuclear facilities. A great majority of the Committee recommended that the regulators be existing agencies, but the Committee did not choose between the U.S. Nuclear Regulatory Commission and the Defense Facilities Nuclear Safety Board, concluding that either one would have to change significantly before it could carry out the responsibilities of a regulator of facility safety at the DOE nuclear complex. The Committee believes that external regulation will increase the assurance of safety at DOE, help restore the credibility of the Department's safety efforts, and increase the efficiency of its operations. The Committee made a number of other recommendations designed to bring about streamlined, effective, and efficient external regulation of safety at DOE nuclear facilities. The recommendations cover such issues as State roles in regulating DOE, public participation, the jurisdictions of the external regulators, and the use of a variety of ways to regulate. The Committee also recommended that DOE maintain a strong "corporate" safety function, to provide assurance that the Department will conform to regulatory requirements, and that any transition to external regulation be managed carefully, so that commendable efforts the Department has made on behalf of nuclear safety are not disrupted. The Department has formed an internal group to evaluate the Committee's recommendations.

INTRODUCTION

The aim of this paper is to give readers a brief overview of the work of the Advisory Committee on External Regulation of Department of Energy Nuclear Safety. The Committee was established in January 1995 by Secretary of Energy Hazel O'Leary. Its Charter assigned it the task of advising the Department, the Office of Management and Budget (OMB), and the White House Council on Environmental Quality (CEQ) on whether, and if so, how, the Department's nuclear facilities should be externally regulated. On January 19 of this year, the Committee's recommendations were made public. The fundamental recommendations were that essentially all DOE nuclear activities be externally regulated by existing agencies, and that DOE retain a strong internal safety management system.

HOW THE COMMITTEE CAME TO BE

The Committee grows out of a long history of concern with the substantial lack of external regulation of nuclear safety at DOE and its predecessors. From the "Manhattan Project" on, nuclear safety at the Department and, before that, the Energy Research and Development Administration and the Atomic Energy Commission has been largely a matter of self-regulation. In the beginning, it could have been no other way, because almost all the expertise was in the Atomic Energy Commission and its contractors. Various federal statutes have long exempted the Department and its predecessors from much of the external regulation to which other federal nuclear facilities and private nuclear facilities are subject. Only since the late 1970's has the DOE nuclear complex been subject to environmental regulation by the Environmental Protection Agency (EPA) and the States, and even now some environmental statutes exempt certain nuclear materials at DOE from external regulation. Only since 1989, when the Defense Nuclear Facilities Safety Board (DNFSB) was

established by Federal statute, has there been any defense complex-wide degree of external oversight of what the Committee calls "facility safety" at nuclear facilities, namely design, construction, operation, modification, and decommissioning. However, the Defense Board investigates and recommends; it does not write or enforce safety rules. (The Nuclear Regulatory Commission (NRC) has had a regulatory role in facility safety at a limited number of DOE sites.) The Occupational Safety and Health Administration (OSHA) has no regulatory role over protection of workers at DOE nuclear facilities, though DOE and OSHA are now studying the possibility of having OSHA regulate DOE.

DOE has a great many nuclear facilities to self-regulate. It manages some 3500 nuclear facilities at 34 individual sites in 13 states. Some of these sites cover hundreds of thousands of acres. The 3500 facilities include uranium separation facilities, chemical processing and reactor fuel fabrication facilities, nuclear production and research reactors, fuel reprocessing facilities, nuclear weapons assembly and disassembly facilities, tritium recovery facilities, nuclear materials storage vaults, some of the world's largest high energy particle accelerators, a fusion laboratory, and a variety of large and small defense and non-defense research laboratories. DOE also manages very large quantities of radioactive materials, including more than 430 metric tons of fissile and non-fissile radioactive materials and isotopes and more than 2,700 metric tons of spent reactor fuel. There are also contaminated inventories of, among other things, roughly 800 million cubic meters of ground water and 60 million cubic meters of contaminated soil.

Self-regulation of such a large and variegated nuclear complex has long been the subject of criticism by outside persons and organizations. An excellent summary of these criticisms was compiled by the Congressional Research Service of the Library of Congress. Two of the criticisms are fundamental: 1) No organization should be permitted to practice "self-regulation" because this inevitably places safety in conflict with primary mission objectives, and 2) self-regulation is particularly ineffective when conducted under a cloak of secrecy. Since the 1980s, a number of Secretaries of Energy, including John Herrington, James Watkins, and now Hazel O'Leary, have worked hard to improve DOE's internal management of safety at nuclear facilities, but the basic issues associated with self-regulation -- particularly the conflict of interest inherent in self-regulation -- have remained.

In early 1994, the House Subcommittee on Energy and Mineral Resources held hearings on proposed legislation to establish external regulation of new DOE nuclear facilities and explore the options for external regulation of existing facilities. At those hearings, Charles Curtis, then Under Secretary of DOE, proposed that DOE initiate a Federal examination of whether and how the Department's nuclear facilities should be externally regulated. In January 1995, DOE established the Committee on External Regulation to conduct that examination. At Secretary O'Leary's urging, the Committee took a broad view of safety, deciding that it should look at all aspects of safety at DOE nuclear facilities: facility safety, worker protection, and environmental protection. The Committee believed that safety requires a coordinated approach encompassing not only radiological protection, but also protection against all hazards at DOE facilities, especially as the Department's emphasis shifts from weapons production to cleanup and waste management,

and chemical and physical hazards to workers come into greater prominence.

THE COMMITTEE'S COMPOSITION AND WORKING METHODS

The membership of the Committee was extraordinarily diverse and very capable. Represented among the 24 members were Federal and State regulatory agencies, national and local citizens' and environmental groups, the nuclear power industry, Native Americans, and labor unions. Among the members were the head of OSHA, the Lt. Governor of Colorado, the acting Provost of the University of California System, and the Chairman of the Chemehuevi Tribe in California. The two Co-Chairs of the Committee were John Ahearne, a former Chairman of the NRC, and Gerard Scannell, a former head of OSHA.

The Committee's work was supported by a small staff of persons drawn from DOE, EPA, and NRC, and by a DOE Internal Working Group formed of persons from most DOE offices. These support efforts were managed by Thomas Isaacs, the Committee's Executive Director.

The Committee conducted its deliberations completely in the open. It held eight two-day meetings at sites across the country, from Washington, D.C. to the Hanford site in the State of Washington. These meetings generated about 4500 pages of transcript, 400 of which were comments from members of the general public. Before each meeting, a team of Committee staff members met with citizens and organizations near the site to encourage their participation. The meetings were advertised in local newspapers and over the DOE system. The Committee set up an 800 number and a World Wide Web site to distribute information about the Committee's activities. The Committee also asked each DOE program office, operations office, and laboratory to tell the Committee what that office or lab thought the major regulatory problems were, and what the solutions might be.

Even before the Committee's first meeting, the Department's Internal Working Group completed several major reports for the Committee, including a compendium of all DOE nuclear facilities, a history of nuclear safety at the Department, an account of the safety laws applicable to DOE nuclear facilities, a description of DOE's many laudable initiatives to improve health and safety at its nuclear facilities, and an account of how nuclear safety at comparable facilities in other countries is regulated.

The Committee itself formed active subcommittees on five subjects: problems with the current system of regulating DOE, what external regulation can and cannot accomplish, worker safety, national security, and options for regulatory models and the distribution of regulatory responsibility. At the Committee's request, the staff wrote papers on several subjects, including enforcement against federal agencies, regulatory models and options, criteria for judging options, contract reform, the role of the public in regulation, and transition issues.

The reports by the Committee, the subcommittees, the staff, and the Internal Working Group are all available from several sources, including the World Wide Web (as of February 2, there had been about 28,000 accesses to the Committee's Web material). The transcripts of the meetings are also available on the Web.

PROBLEMS AND THEIR CAUSES

The Committee found these symptoms of problems in the way safety at DOE nuclear facilities is now being regulated: frequently poor safety practices, which have resulted in costly cleanups and unnecessary exposures; distrust of DOE, in the public, in Congress, and among other

governmental agencies; frustration throughout DOE's work force with a regulatory morass that often impedes efforts to do work both safely and well; numerous cases of non-compliance with established safety requirements; and failure to address hazards by their relative importance.

In the Committee's view, these symptoms have fundamental causes rooted in DOE's approach over the years to safety, and in its regulatory structure. Although the Department has made substantial progress in recent years, the Committee concluded that most of the root causes of the problems remain. In the Committee's view, these causes are: the built-in conflict of interest in self-regulation; the legacy of secrecy that has historically shielded DOE's activities from outside view, thus leading in many cases to safety practices less sound than those used in the private sector; lack of stability in safety management and policy, stemming from the fact that DOE's leaders are of necessity political appointees whose tenures are short; lack of management accountability and inadequately coordinated regulatory and oversight functions; redundant, confusing safety requirements (the Department is working hard to straighten this out); and a lack of balance in addressing hazards, with chemical and physical hazards to workers sometimes receiving insufficient attention, and hazards covered by enforceable sanctions receiving more attention than risk and cost/benefit considerations can justify.

WHY EXTERNAL REGULATION, AND HOW?

The Committee concluded that "it is sound public policy to ensure through external regulation that DOE is regulated to standards and other requirements comparable to those to which the private sector is regulated." More particularly, external regulation can eliminate the conflict of interest inherent in self-regulation and thus assure that safety will receive consistent and adequate consideration; external regulation can thereby help restore the Department's credibility; it can bring increased insulation from political change, and thus increase the stability of safety policy in the Department; it can increase the efficiency of the Department by eliminating the redundancies in internal self-regulation and allowing the Department to focus on its missions; and it can make clearer just who the regulator is, and thus help induce clearer lines of accountability in the Department.

The Committee considered several possible distributions of regulatory responsibility among external agencies. It spent some time articulating an option in which DOE would be regulated by a new agency with plenary jurisdiction over all aspects of safety at all DOE facilities, and with the power to choose the best from existing safety standards and processes, focusing particularly on risk-informed prioritization of hazards, and, where possible, performance-based standards. Some members of the Committee hoped that such an agency might become a model for regulatory reform in the private sector. In the end, however, a large majority of the members decided that it would be less disruptive of existing external regulation of the Department, and less likely to aggravate the wide-spread perception that DOE is getting special treatment, if DOE were regulated by existing agencies. The Committee recommended the following distribution of regulatory responsibilities:

An existing agency -- either the NRC or a restructured DNFSB -- would regulate facility safety at DOE nuclear facilities. (In the Committee's view, neither the NRC nor the DNFSB was at present the kind of facility safety regulator the Committee thought would be best.)

OSHA would regulate all protection of workers at DOE nuclear facilities, unless regulation of worker risks at a given facility could significantly interfere with maintenance of facility safety (for example, if criticality is possible), in which case the regulator of facility safety would regulate all protection of workers at the facility.

EPA would continue to regulate environmental protection for all DOE nuclear facilities.

States with programs authorized by the Federal regulators would exercise roles in environmental protection, worker protection, and facility safety comparable to the roles the States now exercise in the regulation of private nuclear facilities. States would have the authority to set more stringent standards as long as those standards did not unduly hinder DOE's performance of its missions (the Committee took a cue here from the analogous standard in the Occupational Safety and Health Act).

This framework would apply to defense facilities also, with certain limited exceptions. Following the lead of a subcommittee whose membership was almost as diverse as the full Committee's, the full Committee concluded that it was possible and highly desirable to protect safety and national security at the same time. The essential element needed to preserve national security interests is a legislative provision for an effective and prompt method of invoking Presidential authority in the rare case of a conflict that the Department and an external regulator cannot resolve. The Committee made two exceptions to the rule of external regulation of defense facilities. First, to protect the most sensitive design information, the Committee recommended that DOE continue to regulate "nuclear explosive safety", namely the formalized program designed to prevent the accidental or unauthorized detonation of high explosives in proximity to special nuclear material. Second, at least in the early stages of a fully external regime, safeguards and security should be left to DOE, to avoid diluting the new external regulators' focus.

In the Committee's recommended framework, the agencies do not have quite the same jurisdictions over hazards that they have in the private sector. In private sector regulation, the NRC sets some standards for environmental protection and worker protection. In the framework set out by the Committee, the facility safety regulator would be limited to facility safety, except in a limited number of cases involving worker protection. The Committee took this approach for fundamentally two reasons: to avoid disrupting existing external regulation of environmental protection at DOE, and to help assure that radiation hazards to the environment and workers are considered in the context of all hazards to the environment and workers.

Of course, the framework just described would require legislation, and the Committee's final Report contains a list of the legislative implications of these and other recommendations of the Committee's.

OTHER RECOMMENDATIONS

The Committee made several other recommendations, some which would apply whether increased external regulation of the Department comes about or not. The chief of these other recommendations are discussed briefly below.

"Corporate" Safety Function

The ultimate responsibility for safety lies with the regulated party. Therefore, even under external regulation, DOE must retain sufficient resources to assure that it implements policies and practices which are

consistent with external requirements. This is particularly important in the area of worker protection, because OSHA's resources are quite limited. However, if the practice of large, multi-site corporations is any guide, those resources can be modest. Department resources now being devoted to regulatory functions -- standard-setting, inspection, enforcement -- could be moved to the new external regulators.

DOE the Regulated Party

To help assure that the highest level of management of a nuclear facility is in step with regulatory requirements, the Committee recommended that DOE be a regulated party -- for example, the "licensee", or the "permittee" -- at every site, and that contractors at some sites also be regulated parties.

Lead Agency

The Committee urged the complex-wide adoption of a "lead agency" approach, in which DOE would have to deal with only one regulator for any given matter at a given site. The Committee recommended that this approach be "facilitated" by legislation.

Citizens' Roles

The Committee strongly supported giving citizens effective roles at all stages of the regulatory process, from setting standards, to applying them in approval actions like licensing, to enforcement. Concerned that the trial-type hearings conducted by the NRC in nuclear power plant licensing proceedings consume a disproportionate amount of resources, the Committee recommended that legislation provide for a simpler, less formal, hearing process for use at DOE nuclear facilities. The Committee was particularly concerned that federal enforcement against DOE be as effective as federal enforcement against private entities. To this end the Committee recommended that citizens be able to sue the Department for not complying with external safety rules, and that citizens be able to sue the external regulators for not performing their duties.

One Size Does Not Fit All

The Committee strongly recommended the use of a variety of regulatory models, ranging all the way from "audited self-regulation" of the sort now employed by OSHA in its Voluntary Protection Program, to the full licensing proceeding of the sort employed by the NRC in licensing nuclear power plants. DOE's nuclear facilities and missions are too varied to be subjected to the same regulatory model. The Committee also urged the use of performance-based criteria wherever possible, to provide the regulated party with the flexibility to achieve cost-effective solutions to safety problems.

WHAT WILL THIS COST?

Given its limited resources, and the unpredictable nature of some of the possible costs, the Committee was not able to estimate the costs of putting in place the regulatory framework it recommended. After a careful cataloging of DOE's nuclear facilities, and a comparison of what it costs the NRC to regulate whatever comparable facilities there are in the private sector, the NRC estimated that it would need 1100-1600 more FTE and $160 million to $200 million annually to regulate what the Committee recommends be assigned to the facility safety regulator (given the number of facilities to be externally regulated, and the sizes of DOE's budget and workforce, these estimates do not seem unreasonable). The DNFSB did not give the Committee any estimate. DOE was unable to say how much it spends on self-regulation.

However, the Committee did make some general observations on what the likely costs of implementing its recommendations would be. The amount the Department spends on internal oversight should decrease; there will be transition costs; the cost of complying with external requirements may go up in the short term. Each regulator should be ensured the resources it needs to carry out additional responsibilities; regulators without adequate resources are only paper tigers, and a transition to a badly funded regulatory framework will only weaken the assurance of safety and reduce credibility. Nonetheless, the cost of regulatory oversight is a small part of the total cost of meeting any set of safety requirements, and there is a real potential for savings through greater efficiency and productivity in DOE's performance of its missions, once the more straight-forward, credible, accountable, external regime recommended by the Committee is put in place.

TRANSITION

The Department has underway a number of laudable safety initiatives. The Committee urged that these be continued. The Committee also recommended that, pending transfer of regulatory authority from DOE to external regulators, all internal regulatory functions in the Department be consolidated in the Office of Environment, Safety, and Health (OESH). For example, at the present time, program offices must concur in new safety standards; the Committee believes that OESH should have sufficient authority to establish standards independently of the program offices. The Committee also recommended that the transition to OSHA regulation of the Department's nuclear facilities, which the Department has long sought, be expedited. To the DNFSB, the Committee recommended that the Board make its processes more open, for instance by issuing its Recommendations in draft form for public comment.

The Final Report contains several cautions about the transition to external regulation. It will be difficult; it will take time; safety must not become the victim of inattention while everyone waits for the new regulator to take charge. However, there have been similar transitions in the past, and much can be learned from these.

DOE RESPONSE

Secretary O'Leary has formed a DOE working group to recommend to her by March 20 what response the Department should make to the Committee's recommendations. The group is head by Acting Under Secretary Thomas Grumbly. Members of the group will include representatives from the Department of Justice and the other two agencies to which the Committee's Final Report was directed, namely, OMB and CEQ. The Secretary has also directed the Department's working group, in coordination with the external regulators, to come up with an implementation plan by May 15.

CONCLUSION

When the Committee's Co-Chairs transmitted the Committee's Final Report to DOE, OMB, and CEQ, the Co-Chairs said that they were "pleased that this distinguished and diverse Committee, which represented the broad range of interests involved in regulation of DOE, has been able to reach conclusions on the difficult issues it has had to consider." The Committee believes that the external regulatory framework it recommends will clear the path to greater productivity and efficiency within the Department by removing regulatory redundances and overlaps and by ensuring a regulatory framework that remains stable as Administrations and officials change. The flexibility the Committee urged in the regulatory approach through, for example, relying where possible on

performance standards rather than rigid prescriptions will allow a more cost-effective approach to ensuring safety. External regulation can help improve public confidence in DOE and provide increased assurance that its future record of nuclear safety will be free of the mistakes of the past. The full title of the Committee's Report is Improving the Regulation of Safety at DOE Nuclear Facilities, and it is available from the DOE Environment, Safety and Health Information Center by calling 1-800-473-4375. ENVIRONMENTAL RADIATION STANDARDS FOR YUCCA MOUNTAIN

Raymond L. Clark
U.S. Environmental Protection Agency
Office of Radiation and Indoor Air (6602J)
Washington, D.C. 20460-0001

ABSTRACT

The Environmental Protection Agency (EPA) has been given the responsibility of setting site-specific health and safety standards for the potential repository at Yucca Mountain, Nevada. The same legislation that gave the Agency that responsibility, mandated a study by the National Academy of Sciences (NAS) to provide input into the bases for the EPA standards. The NAS has completed and presented a report to the Agency; this paper summarizes the report's recommendations and conclusions. Following receipt of the report, the Agency opened a comment period and held public meetings to gather comments; the major issues from the comments are summarized. Based upon the report from NAS and the public comments, EPA has started formulating proposed standards which will be known as 40CFR Part 197. It is planned for the proposal of 40 CFR Part 197 to occur in the Spring of 1996.

HISTORY

In 1985, the Environmental Protection Agency (EPA), under the authority of the Atomic Energy Act, issued 40 CFR Part 191, Environmental Radiation Protection Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Waste (1). These are generic standards and, as such, apply to all pertinent facilities, including Yucca Mountain (which has since been exempted by legislation, see below), the Waste Isolation Pilot Plant (WIPP), and the Greater Confinement Disposal Facility. With regard to Yucca Mountain, this situation changed seven year later.

In October 1992, two Federal laws were enacted, the Waste Isolation Pilot Plant Land Withdrawal Act (WIPP LWA) (2) and the Energy Policy Act (EnPA) (3). While the WIPP LWA dealt mainly with WIPP, a potential repository, in New Mexico, for transuranic radioactive waste, it also exempted Yucca Mountain from coverage under 40CFR Part 191. At the same time, the EnPA directed EPA "to set generally applicable standards for the Yucca Mountain site...for protection of the public from releases from radioactive materials stored or disposed of in the repository at the Yucca Mountain site." It also directed EPA to contract with the National Academy of Sciences (NAS) to "conduct a study to provide...findings and recommendations on reasonable standards for protection of the public health and safety." In Section 801 of the EnPA, Congress also mandated responses to three inquiries:

"(A) whether a health-based standard based upon doses to individual members of the public from releases to the accessible environment (as that term is defined in the regulations contained in subpart B of part 191 of title 40, Code of Federal Regulations, as in effect on November 18, 1985) will provide a reasonable standard for protection of the health and safety of the general public;

(B) whether it is reasonable to assume that a system for post-closure oversight of the repository can be developed, based upon active institutional controls, that will prevent an unreasonable risk of breaching the repository's engineered or geologic barriers or increasing the exposure of individual members of the public to radiation beyond allowable limits; and

(C) whether it is possible to make scientifically supportable predictions of the probability that the repository's engineered or geologic barriers will be breached as a result of human intrusion over a period of 10,000 years."

THE NATIONAL ACADEMY OF SCIENCES REPORT

In early 1993, the Agency established a contract with the NAS to produce the study required by the EnPA. The Agency received that report, entitled Technical Bases for Yucca Mountain Standards (hereafter called the NAS Report), on August 1, 1995 (4). The NAS divided the results of the study into two categories, recommendations and conclusions. The remainder of this section summarizes the recommendations and conclusions; the interested reader is urged to obtain the entire NAS Report to read the entire rationale.

Recommendations

In the Executive Summary of their report, the NAS recommended:

(a) the use of a standard that sets a limit on the risk to individuals of adverse health effects from releases from the repository;

(b) that compliance with the standard be measured at the time of peak risk, whenever it occurs within the limits imposed by the long-term stability of the geologic environment (which NAS judged to be about one million years);

(c) against a risk-based calculation of the adverse effect of human intrusion into the repository since it is not possible to assess the frequency of human intrusion far into the future; (d) that the consequences of an intrusion be calculated to assess the resilience of the repository to human intrusion;

(e) that in those instances where science cannot provide the guidance necessary to resolve an issue, policy questions should be resolved through a rule making process that allows opportunity for wide-ranging input from all interested parties;

(f) that the critical-group approach for assessing individual risk be used; and,

(g) that EPA require that the estimated risk calculated from a specified, assumed intrusion scenario be no greater than the risk limit adopted for the undisturbed-repository case because a repository that is suitable for safe disposal should be able to continue to provide acceptable waste isolation after the specified intrusion.

CONCLUSIONS

Also in the Executive Summary, the NAS concluded that:

(a) an individual-risk standard would protect public health, given the particular characteristics of the site, provided that policy makers and

the public are prepared to accept that very low radiation doses pose a negligibly small risk;

(b) the physical and geologic processes are sufficiently quantifiable and the related uncertainties sufficiently boundable that performance can be assessed over time frames during which the geologic system is relatively stable or varies in a boundable manner;

(c) it is not possible to predict, on the basis of scientific analyses, the societal factors for an exposure scenario. Specifying exposure scenarios, therefore, requires a policy decision that is appropriately made in an EPA rule making process;

(d) with respect to the second question of Section 801, it is not reasonable to assume that a system for post-closure oversight of the repository can be developed, based upon active institutional controls, that will prevent an unreasonable risk of breaching the repository's engineered barriers or increasing the exposure of individual members of the public to radiation beyond allowable limits;

(e) with respect to the third question in Section 801, it is not possible to make scientifically supportable predictions of the probability that a repository's engineered or geologic barriers will be breached as a result of human intrusion over a period of 10,000 years; and,

(f) there is no scientific basis for incorporating the ALARA (as low as reasonable achievable) principle into the EPA standards or Nuclear Regulatory Commission (NRC) licensing regulations for the repository.

PUBLIC COMMENTS

Shortly after receiving the NAS Report, the Agency opened a comment period and held public meetings to receive comments and to explain the rule making process. The public meetings were held in Amargosa Valley (in Nye County) and Las Vegas, Nevada and Washington, D.C. About 60 comment letters, including about 30 copies of a form letter, were received. There was no transcript of the public meetings; the only formal record of the oral comments that was made is in an EPA summary document (5). The reason for no transcript was that these were not hearings and the feeling that the free interchange of ideas and questions would be encouraged in a less formal atmosphere. The majority of comments and questions were from private citizens. However, there were also comments and questions from Federal agencies, the State of Nevada, Native American groups, several counties, industry groups, environmental organizations, and public interest groups, The major themes of those comments were:

- agreed with the NAS that no system of active institutional controls can preclude human intrusion;
- agreed with the NAS that scientific predictions of human intrusion cannot be made;
- there was a split in opinion on whether a critical-population-dose limit would adequately protect the general population. Those who agreed also pointed out that the final decision must be made through a public-policy making process such as the EPA rule making and that the limit should be set at approximately one chance in a million of contracting a fatal cancer. Those who disagreed had three reasons: 1) use release limits, as was done in 40 CFR Part 191, would avoid dilution; 2) use a limit on maximum-individual and population doses since risk is not an enforceable quantity; and 3) standards should not be lower than in 40 CFR Part 191;

regarding the definition of the critical population group, several considerations were suggested, e.g., base the size and location on the ground-water pathway and assume the high end of potential intake rates; the group could be located in either Nevada or California but at any rate wherever the ground water exits the ground or is closest to the surface; the probability-based critical population group is no understandable; use the subsistence-farmer group;

disagreed with NAS on use of the negligible incremental risk concept, i.e., do not use it in the standards;

there was a split on the NAS suggestion to eliminate subsystem requirements. Some thought they were useful and essential; others thought that there were potentially counterproductive and stifling;

respect the ideology of native people;

how to deal with uncertainty was not sufficiently addressed by NAS;

calculate risk until the peak is reached; one commenter was concerned with being able to show reasonable expectation of compliance over hundreds of thousands of years and suggested that the time frame be much shorter, e.g., 10,000 years;

base the standards on health protection not on the projected containment capability of Yucca Mountain;

the NAS did not give a sufficient justification for not using the ALARA concept;

include doses from the Nevada Test Site and the low-level waste disposal systems in the area;

work closely with the NRC to make standards amenable to licensing; and,

establish an information center closer to Amargosa Valley.

AGENCY ACTIONS AND DIRECTION

The Agency has taken a number of actions to keep the public informed about the Yucca Mountain rule making. It has established a toll-free, 24-hour recording for the rule making which can be reached by calling 1-800-331-9477. There is also EPA's Technology Transfer Network electronic bulletin board which can be reached by calling 919-541-5742 or via TELNET ttnbbs.rtpnc.epa.gov. The Agency is also working to develop a home page on the World Wide Web.

Also, the Agency has taken definitive action on two of the public comments -- the final two listed above. In line with the comment, the Agency and the NRC have each named a technical liaison to facilitate the interchange of technical data and issue resolution. The Agency recognizes that the time limits placed upon it by the EnPA allow only limited, independent, technical analyses and that the NRC has been studying Yucca Mountain for many years. Therefore, the Agency anticipates that NRC will be a significant source of technical data. To date, the liaison approach has proven to be very useful and successful.

As for the final comment, in September, the Agency worked with the staff of the public library in Amargosa Valley to establish an information center. While the intent is to place the same information into it as will be placed into the formal dockets in Washington, DC and Las Vegas, Nevada, the designation of information center relieves the limited library staff from the necessity of keeping a formal, legal file.

The other comments are the heart of the decisions that will need to be made as a result of the rule making. The Agency has taken into account many of the comments as it formulates the proposed standards. However, it is premature to report at this time on the outcome of any particular issue since the Agency has not reached any definitive positions on them.

However, the Agency has two goals. One goal is to set standards that assure both that Yucca Mountain will not open unless it is safe and that it will be able to open if it is safe. The Nation can neither afford to emplace the wastes into a site that is not safe, nor to needlessly abandon a safe site. Another goal is to set standards that are protective of public health and the environment and that are implementable by NRC. Only standards that meet both of these goals will be acceptable to the public. Public acceptance is crucial, without it, nuclear waste disposal programs will fail. The public's perception of the credibility of the Yucca Mountain evaluation could impact all nuclear programs in the U.S.

CURRENT STATUS AND THE NEXT STEPS

The Agency has received the NAS Report, held public meetings, received comments, and is formulating proposed standards, to be known as 40 CFR Part 197. It is anticipated that the proposal will be published in the Federal Register in the Spring of 1996. The next step will be to produce a proposed set of standards and a set of draft background documents. There will then be a public-comment period and public hearings on the proposed standards. This will be followed by final standards, background documents, and a response-to-comments document. These will be completed as expeditiously as prudently possible.

ABSTRACT

The U.S. Nuclear Regulatory Commission (NRC), Division of Waste Management (DWM) has been examining its regulatory strategies for ways to

optimize protection of the public health and safety and the environment while minimizing the burden on licensees from the regulatory framework, all in the face of a declining budget. Based on this examination, NRC staff has revised its regulatory strategies in the areas of uranium recovery (UR), high-level waste (HLW), and decommissioning of Site Decommissioning Management Plan (SDMP) sites.

In May 1993, the staff identified four areas in the UR licensing process which could be revised to reduce the regulatory burden on UR licensees while ensuring the same level of protection to the public and the environment. DWM is now implementing a program which has streamlined the licensing process by: 1) using more flexible license conditions that incorporate license criteria rather than prescriptive, detailed conditions; 2) implementing a performance based license condition approach that allows licensees to make changes to their facilities, under certain conditions, without NRC approval; 3) eliminating dual regulation of in-situ leach well fields by relying on State reviews; and 4) relying on reviews by States concerning cultural artifacts.

In 1995, DWM revised its HLW prelicensing program strategy in response to budget reductions and the U.S. Department of Energy's (DOE's) new program approach for streamlining site characterization, site suitability determination, and licensing. DWM's revised HLW program strategy is still based on the Overall Review Strategy (ORS) developed in 1994, but its implementation has been modified by using a "vertical slice" approach to provide more focused and timely feedback to DOE. The vertical slice approach builds on the strategies in the ORS for conducting prelicensing reviews and for developing review capability that are focused on, and limited to, key technical issues most important to licensing. Each technical issue is addressed with one or more sharp cuts (thus the term vertical slice) encompassing an appropriate range of review and review capability development activities.

DWM recently streamlined decommissioning procedures in a management plan as part of the annual update of the SDMP. This management plan is directed at accelerating remediation of SDMP sites and minimizing the regulatory burden imposed on licensees and other responsible parties. The plan calls for revising current procedures to reduce the amount of NRC effort invested in site characterization and confirmatory radiological surveys. Revised procedures will require, under most circumstances, the staff to review site characterization information and decommissioning plans concurrently. NRC is also revising the procedures by placing a greater emphasis on the termination radiological survey conducted by the licensee or responsible party, with a corresponding reduction in the extent of NRC confirmatory surveys.

This paper will describe in detail the revised regulatory strategies being implemented by DWM in the areas of UR, HLW and decommissioning of SDMP sites. Further, the rationale for the program changes and the advantages and disadvantages of these changes will be discussed.

INTRODUCTION

In an effort to optimize protection of the public health and safety and the environment and minimize the burden on licensees in a period of declining budgets, NRC has initiated efforts to streamline the licensing process in high-level waste, uranium recovery, and decommissioning program areas. In each of these areas the staff has evaluated the regulatory approach and identified improvements directed at enhancing public protection, improving public participation in the regulatory

process, facilitating communication with licensees and improving the timeliness of regulatory actions.

URANIUM RECOVERY PROGRAM

In May 1993, NRC committed to explore ways to reduce the regulatory burden of uranium recovery licensees withoutcompromising protection of health and safety and the environment (NRC, 1994). The staff determined that there were four areas in which the regulatory impact might be reduced. First, licensees could decrease the number of amendment requests by using more flexible "criteria based" license conditions rather than extremely specific conditions, such as conditions that specify particular individuals or organizational structures. Second, licensees could implement a performance based license condition that would allow changes to their facilities, under certain conditions, without NRC approval. Third, NRC staff can rely on State reviews, thereby eliminating dual regulation of in-situ leach facility well fields provided State oversight is comparable to current NRC requirements. Fourth, NRC can rely on State review of Cultural Artifacts to avoid dual regulation. Each of these areas is described in more detail below.

More Flexible License Conditions

The staff believes it is possible to reduce the regulatory burden on licensees by implementing more flexible license conditions. In its review of several license amendments, the staff found that many amendments resulted from extremely specific license conditions. For example, some license conditions specified licensee facilities, organizations and in some cases individuals, with the effect that licensees could not change these condition specifications without submitting a license amendment. The staff has determined that a number of license conditions could be changed to more flexible "criteria based conditions." Such conditions could identify criteria for specific staff positions (such as radiation safety officer) rather than identify specific individuals. Similarly, organizational criteria could be included in the license condition rather than specific organizational structures. However, such criteria based conditions must be specific to individual licenses, and do not constitute generic changes that NRC can make industry-wide, by rulemaking.

Even if criteria based conditions are implemented, there are some license condition changes that could not be made without prior NRC approval. Examples include a change in facility ownership, and a change in control of the license. However, in general the staff believes that criteria based license conditions that would allow licensees to make minor changes without prior NRC approval, are acceptable.

Performance-Based License Conditions

A second area where the staff found regulatory reduction could be achieved was in the preparation of a performance-based license condition. The staff developed a performance-based license condition which is consistent with the Commission's regulations and licenses for other facilities. The performance-based license condition was modeled on the provisions of 10 CFR 50.59, which allow 10 CFR Part 50 licensees to make changes to, or conduct tests and experiments at, their facilities without prior NRC approval unless the change, test, or experiment involves a change in the technical specifications incorporated in the license or an unreviewed safety question. The performance-based license condition is structured such that uranium recovery licensees are required to submit applications for all license amendments, unless it can be demonstrated that the provisions specified in the performance-based license condition

have been satisfied. In addition, the performance-based license condition requires that a summary of all changes made under that condition be provided to NRC in an annual report. Therefore, the performance-based license condition provides the same degree of flexibility contained in the regulations and licenses for other nuclear facilities, and is consistent with established NRC policy.

If licensees decide to incorporate the performance-based license condition into their licenses, they would have the burden of ensuring proper implementation of the condition. Summaries required by the condition coupled with information gained from inspections would allow the staff to determine if a licensee had properly implemented the condition. Improper implementation would result in a violation of the license and the licensee would be subject to possible NRC enforcement action.

NRC's Regulatory Role Over In-Situ Leach Facility Well Fields

The staff also believes a reduction in the regulatory burden of uranium recovery licensees can be realized by eliminating dual regulation of groundwater in in-situ leach well fields. Well fields at in-situ leach operations are also regulated by the U.S Environmental Protection Agency (EPA) and State agencies in non-Agreement States. Based on NRC's evaluations, it is acceptable for NRC to rely on the State's groundwater regulatory program provided the program is comparable to NRC's. This approach would allow the staff to ensure that necessary oversight is being achieved while eliminating dual regulation.

The staff is currently meeting with the States that have NRC licensed in-situ leach facilities to determine whether the States would be willing to provide such oversight and whether the States' programs are comparable to the NRC's.

Archeological Surveys

The fourth and final way the staff proposes to streamline the licensing process is by relying on State reviews of licensee archeological surveys thereby eliminating dual regulation. NRCis required by the National Historic Preservation Act of 1966 and the National Environmental Policy Act of 1969 to evaluate the effects of a licensee's proposed action on cultural resources. However, NRC need not conduct these reviews independently, provided the staff can use reviews conducted previously by the State Historic Preservation Officers.

HIGH-LEVEL WASTE PROGRAM

NRC's revised HLW program strategy for the prelicensing program is based on the ORS (NRC, 1994). The ORS was prepared in 1994 to provide the principal policy guidance to the staff for conducting its prelicensing program and license application review. Using the graded approach established in the ORS, the staff will conduct more detailed reviews, using independent assessment methods and results of applied technical investigations for those technical areas most important to repository performance. Therefore, these key technical issues (KTIs) help focus and link together the staff's work, in all parts of the program, on what is most important to licensing.

The new program strategy, termed "vertical slice" approach, builds on the strategies in ORS for conducting prelicensing reviews and for developing review capability for the 10 KTIs most important to repository performance and licensing (NRC, 1995). To implement the vertical slice approach, the staff will develop a review capability and apply it to reviewing DOE's program in selected areas, on an audit basis. This audit

approach is efficient in times of reduced budgets, yet effective because of its emphasis on resolution of KTIs important to repository performance. Further, additional efficiency is gained by establishing NRC staff work schedules based on providing DOE feedback consistent with DOE's major milestone schedules.

To date, the staff has identified the following 10 KTIs;

1. Unsaturated and Saturated Flow Under Isothermal Conditions
2. Igneous Activity
3. Radionuclide Transport
4. Structural Deformation and Seismicity
5. Thermal Effects on Flow
6. Repository Design and Thermal-Mechanical Effects
7. Evolution of the Near-Field Environment
8. Container Life and Source Term
9. Total System Performance Assessment and Technical Integration
10. Support Revision of EPA Standard and NRC Rule.

In addition, technical needs have been identified for each KTI. Technical needs are the work activities the staff feel must becompleted to address the KTIs. Based on the results of these work activities, the staff will comment on the sufficiency of DOE's site characterization program and evaluate the effectiveness of DOE's overall program for preparing an acceptable license application. Consistent with NRC and DOE meeting agreements, issue resolution will be achieved during prelicensing when NRC agrees with the DOE, at the staff level, on the acceptability and sufficiency of the information for eventual licensing.

Numerous advantages are associated with the vertical slice approach. First, the HLW program is focused by giving priority to those staff activities related to the most important licensing issues, and providing timely feedback to DOE. Second, integration of the NRC program is improved by coordinating the necessary activities and technical disciplines needed to prepare for and conduct reviews of each issue. This audit approach will also efficiently evaluate a wide range of DOE activities and how well they are integrated for use in licensing. Finally, in a time of declining resources, this approach is an efficient use of limited resources.

As with any program approach, the vertical slice approach has some inherent weaknesses. By focusing all the staff's prelicensing reviews on KTIs, many parts of DOE's program and associated sections of DOE documents will not be reviewed by the staff before submittal of the license application. Therefore, the license application may be incomplete, resulting in delays for the staff's acceptance review, for docketing the license application and for the compliance review. Another weakness is that by focusing on KTI's, the staff may overlook other potential licensing vulnerabilities in its reviews.

Despite its weaknesses, the staff believes the vertical slice approach is an effective and efficient way to streamline NRC's HLW repository program in response to declining budgets and changes to DOE's program.

DECOMMISSIONING PROGRAM

NRC staff is currently streamlining the decommissioning regulatory program, while ensuring effective oversight of decommissioning projects listed in the SDMP and other significant decommissioning actions at nuclear materials facilities (NRC, 1995). Regulatory streamlining is focused on revising existing procedures to reduce NRC effort devoted to site characterization reviews and confirmatory radiological surveys.

Site characterization

Under existing policies and procedures, NRC staff typically reviews site characterization plans and site characterization reports to ensure that licensees have established the extent and type of radiological contamination present before developing decommissioning plans. The staff plans to change the existing procedures for most sites by delaying the review of site characterization information until after the decommissioning plan is developed and submitted for review. This approach promotes a more coordinated and focused review of site characterization information because reviewers will be compelled to emphasize issues that affect the selection and implementation of a decommissioning approach. In most cases, reviewing the characterization data and the decommissioning plan concurrently will allow NRC staff to initiate the decommissioning plan review earlier and allow for parallel resolution of characterization and decommissioning issues which, in many cases, are interdependent.

Confirmatory Surveys

Currently, at the conclusion of remedial actions, a licensee or site owner conducts a termination radiological survey to demonstrate that residual radioactivity levels have been sufficiently reduced in accordance with NRC criteria. NRC then conducts a confirmatory survey to verify, on an audit basis, the results of the licensee's termination survey. These confirmatory surveys are discretionary for NRC; since regulations do not require confirmatory surveys. However, in recent years confirmatory surveys have become routine for SDMP sites.

In the future, the staff intends to reduce the number of NRC confirmatory surveys by placing greater emphasis on the quality of licensee's termination radiological surveys. Some level of confirmatory surveys will continue to be performed at each site. The extent of NRC's confirmatory surveys will be based on past licensee performance, on the result of NRC inspections of the licensee's survey while in progress, and on the results of the licensee's quality assurance/quality control efforts as reported in the termination survey report and as observed during inspections.

The staff is working with the EPA, DOE and Department of Defense to develop comprehensive guidance on performing termination surveys. This guidance should provide users with a method of performing and documenting termination surveys that will result in higher quality, more defensible termination survey data. The staff believes that higher quality licensee termination surveys will reduce the need for NRC confirmatory surveys.

CONCLUSIONS

In a period of constrained resources in both the public and private sectors, NRC staff is making every effort to optimize protection of the public and the environment while streamlining regulatory programs and minimizing unnecessary burdens on licensees. The staff is acting to make significant flexibility available to uranium recovery licensees if the licensees choose to file amendments that make their licenses more criteria-based. These changes are specific to individual licenses, and do not constitute generic changes that NRC could make industry-wide. In addition, the staff has developed a generic performance-based license condition that can be added to existing licenses, should licensees file an application for amendment to include this condition. The staff is pursuing the potential of eliminating dual regulation of in-situ leach well fields and cultural resources. Eliminating dual regulation can be

achieved in States where the staff finds that State oversight of the facilities is at least equivalent to that of NRC.

In HLW, a vertical slice approach has been developed to streamline NRC's repository program in response to declining budgets and changes to DOE's program. The vertical slice approach focuses on resolving KTIs with DOE, prioritizing staff activities based on issue resolution, improving the integration of all activities, and simplifying and orienting both NRC and DOE products toward what is needed for an acceptable license application. Prelicensing activities will focus on resolving KTIs with DOE at the staff level. The staff will then evaluate the overall effectiveness of DOE's program for preparation of an acceptable license application.

NRC staff efforts to streamline the regulatory process associated with the decommissioning of SDMP sites is focused on revising existing procedures for reviewing site characterization and confirmatory radiological surveys. These revisions will reduce NRC's level of effort applied to SDMP site regulation, while ensuring public and environmental protection.

ABSTRACT

At The C.E.A., ceramic type materials are subject of active R&D programs to improve the conditioning of radioactive wastes. The conditioning of low or medium-level activity wastes is based on the tailored ceramics concept. $NaNO_3$ rich evaporator concentrates would be conditioned in nepheline $NaAlSiO_4$; $BaSO_4$ rich precipitation sludges, in the perovskite structure $BaTiO_3$. The conditioning of selectively extracted long-life radionuclides is envisaged in phosphate matrices; minor actinides and iodine in apatite structures, plutonium in monazite one.

INTRODUCTION

Conditioning of radioactive wastes in ceramic type materials formed subject of extensive R&D programs between '75-'85 (1). Nevertheless,

these efforts were brought to a halt afterwards. In France, the act of 30 December 1991 has since instigated new interest in this type of conditioning (2). Indeed, its guideline 3 encourages long-life and high activity radioactive wastes to be scrutinised by long-life surface storage and conditioning procedures. The C.E.A. (Commissariat l'Energie Atomique, French Atomic Energy Commission), D.E.S.D. (Dpartement d'Entreposage et de Stockage des Dchets), is developing a R&D program within this framework. These efforts are carried out in compliance with recent C.N.E. guidelines (Commission Nationale d'Evaluation) (3). This program aims to propose mineral matrices with performances higher than those of traditional ones (bitumen, cement, polymers), for the conditioning or medium-level activity wastes (B wastes as per the French classification), on the one hand. On the other hand, it aims at evaluating the feasibility and performances of crystalline matrices designed to condition selectively extracted long-life radionuclides. We shall discuss of "ceramisation" in the first case, and of "insertion" in the second one. Low-level activity wastes (A wastes) are equally concerned by ceramisation.

RESULTS

Ceramisation

Ceramisation primarily concerns B wastes (low thermal power, a activity >3.7 GBq.t-1) destined for geological disposal. These B wastes contain few radioelements; their mass being essentially made up of non radioactive additives. High activity wastes (C wastes) are presently satisfactorily conditioned in glass, however ceramisation could be a promising procedure for the conditioning of forthcoming sodium rich wastes.

Ceramisation is based on the "tailored ceramics" concept, developed in the 1980's by Harker et al. (4). The idea is to add chemical reagents to the waste in order to form a "customized" crystalline phase which, after consolidation, resembles a natural mineral of proven stability over geological periods ("natural analogue" concept). The final product is thus a matrix of high chemical stability, with improved long-term behavior. Furthermore, a judicious choice of the mineralogical structure to be formed allows optimal use of the waste's chemical constituents, minimization of the quantity of additives, and thus leads to a ceramic having a high waste incorporation rate, and a significant reduction in the conditioned waste's volume. As B wastes should make up the essential of deeply disposed wastes in the future, this second objective meets both economic and safety concerns as well as the concern to rationalize and optimize the management of geological disposal. Finally, as all ceramisation procedures included a high temperature waste calcination step, the products considered downstream from this operation will be chemically inert products; hence the increased safety and security of the conditioning procedure.

The advantages of the ceramisation procedure previously mentioned are in fact conclusive advantages, when choosing a B waste conditioning procedure. Nevertheless, they also merit to be taken into account when choosing a conditioning procedure for A wastes; wastes which will be disposed for 300 years in a surface facility. We shall present two examples where ceramisation can be applied, one concerning A wastes: the evaporation concentrates from a STEL (Station de Traitement d'Effluents Liquides, liquid waste processing facility); and the other, B wastes: precipitation sludges derived from decontamination processing of liquid

effluents from a reprocessing plant. Emphasis is placed on the original technical results obtained.

Ceramisation of evaporator concentrates originating from STEL

The purpose of the work undertaken is to substitute the conditioning of STEL evaporator concentrates by bitumen encapsulation with mineral packaging. In reality, this entails the design of a new industrial facility ensuring a highly stable conditioning process which allows, in addition to manufacturing safety, a reduction in the volume of packages intended for surface disposal. This concentrate takes the form of the very concentrated solution containing approximately 300 g.l-1 of mineral salts; its activity level is in the order of 0.15 GBq.l-1, the principal radionuclides being 137Cs and 60Co.

The average composition of the dry extract of this concentrate is:

NaNO3 81%
Na3PO4, 12H2O 6%
K3PO4, 2H2O 6%
NaCl 2%
Na2SO4 2%

In reality, the observed anion concentrations fluctuate considerably and batches rich in sulphate and phosphate are sometimes encountered. On the contrary, the cationic load of the concentrate, essentially made up of alkalines, is relatively constant; alkaline-earths being present only as minor compounds. Therefore, we have chosen the nepheline structure NaAlSiO4. This is a natural mineral which was extensively studied in the framework of the conditioning of sodium rich radioactive wastes, in particular for certain Synroc formulations (1). This compound has a resistance to water leaching that is perfectly compatible with the 300 year surface disposal period, as well as a capacity to incorporate a significant amount of sodium (21% Na2O). Furthermore, its structure allows sodium to be substituted with caesium.

In order to ceramise the nepheline waste, the essential problem that needs to be solved is the quantitative elimination of initially present anions (5). Obviously, this operation must be carried out without loosing radioelements. The direct calcination of the waste is not adapted to this as it leads to pronounced volatilization of the sodium, in oxide form, and especially of the radioactive caesium. One solution consists in treating the waste with oxalic acid H2C2O4, in the presence of Al2O3 and SiO2 additives. Drying of the transformed waste results in the elimination of nitrates, in HNO3 form, leading to a dry residue that is essentially made up of alkaline oxalates. Heat treatment of this residue leads to the formation of carbonates, near 400C, then to the reaction of these carbonates with silica and alumina, up to approximately 850C, producing alkaline aluminosilicate. The tests performed on simulated samples, according to the preceding composition, and doped with non radioactive cobalt and caesium, show that all the sodium initially present in the waste is found in the final compound. The quantity of the residual nitrates is in the order of 1% of the initial quantity. Lastly, all of the caesium and cobalt is confined in the final material.

The consolidation step is carried out after the powder is crushed and pressed to 100 MPa. Sintering takes place towards 1,100-1,200C (6). The study by X-ray diffraction of the ceramic obtained, using a typical-mean composition concentrate, only allows the nepheline phase to be detected. However, tests conducted on simulated wastes, highly loaded in sulphate and phosphate, show that the pre-treatment does not allow the

quantitative elimination of these anions. The presence of sulphate in particular, leads to secondary phases during sintering, especially nosean Na8Al6Si6O24SO4. Studies are underway to evaluate the confinement characteristics of this particular phase.

Various batches of real radioactive concentrates, sampled from STEL storage tanks, were ceramized according to the reference protocol (5). These tests showed that the quasi-whole of radioelements present in the waste were confined in the final ceramic: 100% yield for 60Co, 137Cs and 90Sr (6). Furthermore, the resistance to water leaching of the samples was tested according to the protocol in use for the surface-disposed wastes (static test, 23C, variable duration). These results were compared to those for a waste conditioned in bitumen. The leaching rate of 137Cs at 90 days is between 0.6 and 2.2 10-3 g.m-2.d-1; it is approximately 100 times lower than that observed for conditioning in bitumen. For the other elements or radioelements, the improvement is even more spectacular: a factor 150 for 90Sr, 3,000 for 60Co and 80,000 for non-radioactive sodium (6).

Finally, the mean factor of observed volume reduction, for ceramisation with regards to bituminization, is in the order of 4.5. Optimization or ceramic densification should allow reduction factors to be obtained in the order of 5.3 (6).

Ceramisation of reprocessing precipitation sludges

During the reprocessing of irradiated fuel, high activity solutions (which contain fission products) are generated, together with low and medium activity effluents. In France, at La Hague, these effluents are decontaminated by a coprecipitation procedure and radioactive sludge is obtained (B waste). 137Cs, 90Sr, 106Ru and 125Sb are the main radionuclides present in the waste which also contains significant quantities of a emitters. This sludge was still very recently conditioned in bitumen. Ceramisation of this waste was examined as an alternative route for its conditioning, and work has been conducted using inactive simulated sludge (7).

The main constituents of this sludge are:

BaSO4	68%
NaNO3	12%
Fe(CN)6Ni2	8%
CoS	9%

Simple heat treatment of this sludge, in air at 900C, leads to decomposition of all products into oxides, except BaSO4 which decomposes to BaO at approximately 1,500C. Moreover, BaSO4 does not have water leaching resisting characteristics.

Therefore, the main problem that needs to be solved to ceramise the waste concerns elimination of sulphates which must be obtained at a low temperature, compatible with the confinement of radionuclides in the final material. This problem, and that concerning the choice of the final conditioning, were solved according to the "tailored ceramic" concept by adding TiO2 to the waste. Indeed, adding this compound to the waste during its calcination in air led, from BaSO4, to the formation of BaTiO3 of perovskite type structure. This structure is that of one of the Synroc's essential constituents: CaTiO3; it is capable of incorporating the main radionuclides present in the waste and corresponds to the "natural analogue" approach discussed previously (1). This calcination reaction can lead to the total conversion of BaSO4 into BaTiO3 (yield near 100%). Its precise mechanism, which implies the formation of an

intermediate reaction product $BaTi_4O_9$, was clarified (8). The temperature of this reaction (near 1,200C), nevertheless remains too high; it is capable of leading to:

- volatilization of radioactive species or sodium oxide,
- pronounced pre-sintering of the precursor powder.

So, the reaction of $BaSO_4$ with TiO_2 was studied in a reducing agent environment (Ar/H_2 5%). In these conditions, the formation of $BaTiO_3$ is obtained near 850C; however, this reaction is hindered by the reduction of $BaSO_4$ to BaS. The formation yield of $BaTiO_3$ is near 80%. As BaSis extremely sensitive to leaching by water, its presence must be avoided. A solution consists in working in a humid atmosphere. In these conditions, BaS can be quantitatively transformed into BaO, which reacts strongly with TiO_2 giving $BaTiO_3$. The corresponding yield is near 100%. Identical results are obtained from the simulated sludge for which the main secondary phase obtained is $Na_2Ti_3O_7$. The powder obtained can be pressed and sintered directly without crushing.

The sintering of this powder can by conducted advantageously in a neutral atmosphere (Ar), at low temperature (1,100C), resulting in a relatively dense ceramic (open porosity 4%). Sintering in air must be avoided as it leads to a less dense material (open porosity 10%), at a higher sintering temperature, and with the appearance of new crystalline phases.

The ceramic's resistance to water leaching, resulting from the transformation of pure $BaSO_4$, was tested according to the standard MCC1 protocol (static test, deionized water, 28 days, 90C). The leaching rate of barium is 0.2 g.m-2.d-1 for a pellet of 10% open porosity, although only 0.05 g.m-2.d-1 for a pellet of 1% open porosity obtained from a higher quality powder. These performances can be compared with those of nuclear glass (9) and are, in fact, much better than those obtained with a conditioning matrix of bitumen type.

The preliminary results presented above allow us to define and propose a process for making a ceramic of high confinement capacity from reprocessing plant waste, at a low temperature compatible with the confinement of radioelements in final conditioning. Tests with real radioactive wastes would now be planned.

Insertion

The separation of long-life radioelements, from high activity solutions, is studied within the framework of guideline 1 of the act dated 30 december 1991, that indicates that work must be conducted on the "search for solutions allowing the separation and transmutation of long-life elements present in high activity and long-life wastes" (2). These studies are performed at the C.E.A. within the larger framework of the SPIN program (Sparation-Incinration, separation-incineration) (10); they aim at diminishing the radiological hazards that these radioelements represent, in the long-term. However, this kind of objective can equally be obtained by improving the confinement of these wastes. The insertion studies conducted at the D.E.S.D. reside in this second opinion, which is encouraged by the C.N.E. (3). They aim at developing specific conditioning matrices, having a very high confinement capacity for long-life radionuclides, after separation. The radioelements a priori concerned by these studies, are the minor actinides Am, Np, Cm; and very long-life fission products, mainly 135Cs, 99Tc, 129I, 93Zr, 107Pd (3, 10). Some of these products, such as iodine and neptunium, are already, or could be separated by the PUREX process.

The materials studied at the D.E.S.D. are phosphate (or vanadate) matrices of apatite or monazite type (11). The apatites form a family of compounds having the general formula $Me_{10}(XO_4)_6Y_2$, where Me represents a divalent cation, XO_4 a trivalent anion, and Y a monovalent anion. The most well-known representative of this family of compounds is phosphocalcic fluorapatite $Ca_{10}(PO_4)_6F_2$. The monazite is a lanthanide (Ln) phosphate: $LnPO_4$, where Ln is mainly La and Ce.

In general, these compounds are characterized as having very low solubility in water, retrograde in temperature, high chemical and thermal stability, and a strong capacity for self-healing of irradiation defects. In this respect, certain natural or synthetic apatites show a quite remarkable, even unique, capacity to have their irradiation defects annealed at a temperature as low as 100C (i.e., the "closing" temperature of fission tracks) (for comparison, the "closing" temperature is 250C for sphene, and 300C for zircon) (12, 13).

These minerals, monazites in particular, formed the subject of advanced studies on the conditioning of high activity wastes and proved to be matrices that are particularly well adapted to the conditioning of Rare Earths and actinides (1, 14). Furthermore, extensive substitution possibilities exist within the apatite structure which allow us to envisage wider usage of these materials for the conditioning of long-life radioelements.

Monazites and britholites (silicated apatites resulting from coupled substitution (Ca^{2+},PO_4^{3-}=Ln^{3+},SiO_4^{4-})) exist in the form of natural minerals which can contain significant amounts of Rare Earths and uranium/thorium (1, 13). The age of some of these minerals can be evaluated at several millions of years. The studies conducted at the natural reactor site of Oklo, Gabon showed the existence of silicated apatites that crystallized during nuclear reaction 2 billion years ago (15, 16). Furthermore, it can be proven that these minerals behaved, with respect to certain elements such as plutonium, Rare Earths or certain fission halogens, as stable trapping and confinement structures, over geological time periods and in conditions of particularly intense irradiation. Thus, at present, these apatites make up the most "natural analogue" example of a waste conditioning material. For a synthetic product formulated in an identical manner, such an established fact provides a serious guarantee concerning its long term behavior and forms a substantial argument in the choice of such compounds.

Here, we present the state of study progress on the conditioning of iodine 129 and minor actinides Am and Cm. Furthermore, the problem of conditioning plutonium will be briefly discussed. Plutonium is a recyclable material, and the best use that can be made of it is to recycle it to produce energy. However, its conditioning could be an alternative allowing for more flexible management of stocks, which could be created following disarmament agreements.

Conditioning of minor actinides

The conditioning of minor trivalent actinides, Am and Cm, is presently envisaged in silicated apatites of the same type as those which can be found at Oklo (17). As with lanthanides, trivalent actinides can be incorporated into the apatite network, thanks to the substitution of phosphates with silicates. Experiments are presently being conducted using Nd^{3+} or La^{3+}, classic inactive simulating of trivalent actinides (11, 18).

The introduction of silicates into phosphocalcic fluorapatite structure was accomplished through a solid-solid reaction at high temperature (between 1,100 and 1,400C, temperature being all the higher as the quantity of silicates to be incorporated is high). Synthesis is carried out from a mixture La2O3/CaF2/SiO2/Ca2P2O7/CaCO3, according to the global reaction:

x/2 La2O3 + CaF2 + 3 CaCO3 + x SiO2 + (6-x)/2 Ca2P2O7
Ca10-xLax(SiO4)x(PO4)6-xF2 + 4 CO2

with x = 1,2,3,4,5,6.

Characterizations by X-ray diffraction and infrared spectrometry show that the total substitution of phosphates with silicates was possible and that a solid solution exists (pure apatite phase) between the poles Ca10(PO4)6F2 and Ca4La6(SiO4)6F2. Similar results were obtained from neodymium. Moreover, the synthesis of oxyapatite Ca10-xLax(SiO4)x(PO4)6-xO was equally accomplished. The tests currently being conducted aim at evaluating and quantifying the resistance to water leaching, and the irradiation self-healing capacity of these synthetic materials.

Conditioning of Plutonium

The conditioning of plutonium presents a specific problem as the matrix envisioned must provide guarantees, not only concerning its long term stability, but also concerning non proliferation. Preliminary incorporation tests were conducted with uranium (+IV) which satisfactorily simulates plutonium (+ IV). Monazite was considered as it has interesting characteristics (1):

- difficulty of recovering plutonium by chemical solubilizing treatments,
- possibility to incorporate actinides in large proportions,
- possibility to easily incorporate gadolinium to deal with criticality problems.

Uranium doped monazites were made through a humid route process, followed by calcination in a reducing atmosphere Ar/H2 5%. Charge balance was obtained by substitution (Ce3+,Ce3+=Ca2+,U4+), and it was established that a solid solution exists from CePO4 to U0.5Ca0.5PO4 (12). The resistance to water leaching of these materials was evaluated by a Soxhlet test (dynamic test, deionized water, 58 days, 95C). The uranium release rate was in order of 0.01 g.m-2.d-1, regardless of the sample's uranium content. This dissolution is incongruent.

Systematic investigations of the synthesis via humid route were performed to correlate the precipitation conditions to the quality (morphology and chemical composition) of the powders obtained, as well as to the densification of the final ceramic (19, 20). These tests proved to be very delicate and led us to develop an original dry route process (21). This is based on the use of an intermediate compound, lanthanum metaphosphate La(PO3)3, as a reaction product to synthesize the monazite. The global solid-solid reaction can be expressed:

- for a tetravalent actinide (Ac):

La(PO3)3 + 3x AcO2 + 3x CaO + (1-3x) La2O3
3 La(1-2x)AcxCaxPO4

- for a trivalent actinide (Ac):

La(PO3)3 + x Ac2O3 + (1-x) La2O3
3 La(1-2x/3)Ac2x/3PO4

This synthesis is performed without a by-product, in particular gaseous by-products. According to our first experimental results, it can implemented, after pressing, by reactive sintering and leads to good quality ceramics (95% of the theoretical density). This procedure thus

minimizes the active steps; only 3 steps: mixing/crushing of reagents, pressing and sintering.

Conditioning of Iodine

The fission iodine (essentially 129I) is separated by the PUREX procedure in the reprocessing plant. Only a small fraction of this species is trapped on a solid support, the rest being discharged to sea. Discharge to sea being presently permitted, studies concerning iodine conditioning find their justification in the zero discharge objective aimed by reprocessing plants. This conditioning procedure should be able to be implemented downstream from a iodine trapping procedure, studied by the C.E.A., which leads to a lead iodide precipitate. This work was conducted from natural iodine, considering an apatite matrix (22, 23).

The choice of the apatitic compound is dictated by steric considerations; in particular, the significant size of the I- ion, and by the fact that the iodated waste to be conditioned will very likely be PbI2. The matrix chosen is vanadium-lead iodoapatite: Pb10(VO4)6I2, which can be obtained through solid-solid reaction (700C for 3h) in a closed environment:

$$3\ Pb_3(VO_4)_2 + PbI_2 \quad Pb_{10}(VO_4)_6I_2$$

Unfortunately, this product decomposes in air starting at 450C, according to the opposite of the preceding reaction, and cannot be correctly densified by natural sintering.

The technological solution which was tested and retained is a reactive sintering under pressure (24). The PbI2 pellet is placed in the center of a mould containing Pb3(VO4)2 in excess. Then, the assembly is sintered at 700C under 25 MPa. The product obtained is a dense matrix having good mechanical strength, composed of a core-formed iodoapatite, encased in sintered Pb3(VO4)2. These compound ceramics were made without iodine loss. The tests currently being conducted aim at optimizing the hot-pressing procedure with respect to the mechanical strength of the so-obtained composites, and quantifying the resistance to water leaching of the conditioning (measurement of the iodoapatite solubility in water in particular).

CONCLUSION

The conditioning of radioactive wastes in crystalline matrices is a present-day topic at the C.E.A.. These tests are being conducted in the framework of the act dated 30 December 1991. For B (and A) wastes, the objectives relate to an improvement of conditioning confinement properties, on the one hand, and to a reduction of the conditioned waste's volume, on the other hand. For separated long-life radioelements, the objective is essentially to significantly improve the confinement properties of the final conditioning. In the first case, the approach developed is of the "tailored ceramics" type; in the second case, the choice of the matrices is dictated by the "natural analogue" approach, the accent being placed on the recently obtained results in the study of minerals formed at the Oklo site. Extensive progress has been made in these two fields. Along these same lines, experimental resources, such as the "Btiment Moyenne Activit" (medium activity building) partly devoted to actinide conditioning experiments, are installed at Cadarache, and modelling studies on new conditioning matrices are underway.

ABSTRACT
The vitrification process is being universally considered the accepted solution for the treatment of highly radioactive material in order to meet regulatory requirements. Also, vitrification of low and intermediate level radioactive material has recently been considered.

A major and most critical unit in the vitrification process so far is the glass melter. The melter operates at high temperatures of around 1150C; it has a large hold-up of material thus requiring long start-up and shut-down times in the range of 3-4 weeks; it releases volatile radioactive gases and the homogeneity of the glass it produces is sometimes questionable. The melter has to be replaced every two-three years on the average which is a disturbance to the process as well as being costly. In this paper an alternative unit to the glass melter, i.e. the extruder-melter is proposed. This unit is a modified plasticating extruder that would produce a complete mixing, melting and homogenization process, and would eliminate most of the inconveniences mentioned above with the glass melter as well as would reduce the cost of investment and operation. Based on the inherent properties of the extruder-melter such operating conditions as the temperature of the melt, the hold-up of material in the unit, the start-up and shut-down times and the volatiles released by the melt could be significantly reduced. Also, the product would be homogeneous due to good mixing of the melt in the extruder-melter. This application would require the development of an extruder-melter that would operate at high temperatures needed for the vitrification process, but would be lower than those used in a glass melter. Three extruder-melters could be operated in tandem so that particulate mixing and evaporation could occur in the first extruder, nitrogen oxide could be released in the second extruder and the glass could be formed in the third extruder. Twin-screw extruders, tapered extruders and other commercially available extruders should be evaluated for the proposed process.

The extruder-melter process could be tested first by using a model compound in the range of temperatures that existing extruders can handle. At a later stage, when an extruder-melter at high temperature operation is developed, experiments could be made with non-radioactive compounds in order to test the applicability of the unit to the real vitrification process.

Model compounds could also be used to determine the applicability of the extruder-melter for the elimination of water and nitrogen oxide from the aqueous slurries and the nitrates before real systems are tested. A reduction of the volatile Cesium oxide is expected due to both lower operating temperatures for the melt and the higher pressure that can be developed by the extruder-melter.

INTRODUCTION

During this last decade, the problem of high level nuclear waste has received much attention and a number of plants are being constructed or considered for construction for processing the high level nuclear waste materials. The immobilization method pursued by the DOE for nuclear waste from Defense Sites is the vitrification process. The radioactive elements present in the nuclear waste are dissolved or dispersed in a practically unleachable borosilicate glass, which in turn is encapsulated in stainless steel canisters and stored in repositories. This basic process is being considered for all US Defense nuclear waste treatment plants, even though the waste compositions are not the same in each plant. Also, other countries are using or considering using this means of treatment of their high-level nuclear wastes. Vitrification plants in the United States include two which have been built, and others which are in the design or construction stage. The first plant is the West Valley Demonstration Plant (WVDP) at the Western New York Nuclear Service Center

at West Valley, New York which has operated for five years at the high temperature needed to produce the glass. The Defense Waste Processing Facility (DWPF) has been constructed at the DOE Savannah River Plant at Aiken, South Carolina. Cold startup was scheduled to begin at the end of 1991 (Weisman et al., 1988). Conceptual designs have been made for the Hanford Waste Vitrification Plant (HWVP) at Hanford, Washington. Operation is not expected until the end of this century (23).

France has been leading the world in full industrial scale utilization of vitrification technology. They completed their second plant which began operation in 1990. The melters are designed to operate 2000 hrs with a replacement time of 48 hours. (Maillet and Sombret 1988 and Jouan et al. 1995). The British built a plant of the French design with two lines and started operation in 1990. (Eldsen and Woodal 1988). Germany, Japan, and Italy followed the same approach for the vitrification process (Tsuboya and Tsumoba 1988 and 13). The concept of incorporating a mechanical stirrer in the glass melter is being developed (3). Thus, the vitrification process is considered today as the solution to the nuclear waste material problem and shall probably be the accepted process for the foreseeable future. In fact the vitrification process may also become the preferred option for treating lower levels of nuclear waste and even other types of hazardous waste (3).

For the vitrification processes considered by the various plants, an extruder-melter could be utilized instead of the glass melter, which has the potential of making significant improvements over the glass melter in the areas of operating temperatures, material hold-up, mixing, start-up/shut-down times and economics.

TECHNOLOGICAL BACKGROUND

Vitrification in the U.S.A.

Several plants for vitrification of high level nuclear waste are being tested, constructed, or in the development stage in the USA as mentioned before. Also, a pilot scale radioactive liquid-fed ceramic melter (RLFCM) was operated by Pacific Northwest Laboratory (PNL). The Defense Waste Processing Facility (DWPF) at the Savannah River Plant was considered as a prototype plant for testing the process and equipment. This plant was used for testing under the Integrated Cold Run Program, before using radioactive material, including the testing of mixing conditions in the melter (Gentilucci 1989). The West Valley Demonstration Project (WVDP) is using a process similar to the DWPF for the vitrification of the commercial nuclear waste stored at the Western New York Nuclear Service Center (WNYNSC) (7,8). Although the waste composition is different the principle for vitrification is the same. However, special tests had to be made for the determination of the proper waste composition in each case and the characterization of the glass produced (Feng et al. 1988). Details on the facility and the demonstration project are described (6).

The Hanford Waste Vitrification Plant (HWVP) took advantage of the knowledge and experience gained from the DWPF and the WVDP. Experience from German and Japanese projects were also incorporated (23). The Idaho Chemical Processing Plant (ICPP) for high-level radioactive waste, located at the Idaho National Engineering Laboratory (INEL) in Idaho Falls, is developing an alternative process to the current glass melter. A waste immobilization plant is being considered for the waste disposal sometime in the year 2011. The new technology that INEL is developing is the Hot Isostatic Press (HIP) where calcinated waste used for feeding an isostatic compactor along with the glass frit (12).

For the vitrification project, the Department of Energy has sponsored the construction and operation of a pilot-scale radioactive liquid-fed ceramic melter operated by Pacific Northwest Laboratory (PNL) at the Radiochemical engineering facility at Hanford (4). This plant served as a pilot plant for the various vitrification plants under construction in the U.S.A. and Germany and has the major components considered by DWPF, WVDP and HWVP, such as a liquid-fed ceramic melter and a canister turntable. Various radioactive compositions of feed were used for the production of the borosilicate waste glass. The operation was terminated in 1987 (10).

Vitrification In Other Countries

The vitrification process for treatment of high level waste has been applied or is being considered in many other countries in the world as well, among them France, England, Germany, Japan and Italy (13,16). These developments are documented elsewhere and are not reviewed here.

Nuclear Wastes, Frit and Waste Glass Compositions

Nuclear wastes vary in their compositions and therefore different glass frit compositions are necessary in order to obtain the desired waste glass compositions. The variations in the frit and nuclear waste compositions affect the waste glass properties such as viscosities, densities, leachability, etc. In the glass making process the temperature is determined by the viscosity necessary for producing the proper mixing to achieve satisfactory homogeneity. In the joule-heated melter the temperatures are high at around 1150C. We believe that the extruder melter can handle materials of much higher viscosities and that lower operational temperatures, in the range of 900C, can be anticipated. Times required for the chemical reactions forming good glass are much smaller than the residence times that are obtained in present melter designs (2). In fact, most of the local homogenization occurs at the temperature of 850C which confirms that the
temperature in the melter of 1150C is needed more for the mixing by convective flow than for the glassification process.

The Glass Melter

The melter operates at a high temperature of about 1,150C and has a large material hold-up. Because of the harsh conditions in the glass melter, this unit must be remotely replaced about every two to three years. Due to the high inventory (hold-up) in the melter and the very high temperatures, the start-up time is very long, normally in the range of 3-4 weeks. The mixing in the melter is obtained by thermal convection (no internal mixers), thus the homogeneity of the product is questionable. The main reason for the high temperatures prevailing in the glass melter is the need for lower viscosities to promote good convection flow. These high temperatures are the cause for a higher rate of evaporation of Cs2O, which strongly contaminates the off-gas system of the glass melter. Recently the idea of introducing a mechanical mixer that would produce a better quality glass, a higher production rate and lower temperatures in the melter of only 1050C was reported by Bickford et al. (3). Some of the problems encountered with large melters were given by Parsons (17).

FUNDAMENTALS OF EXTRUDER-GLASS MELTER

Extruder Characteristics

Extruders are remarkable machines. They are rugged in construction and reliable in performance. Single screw extruders are not positive-displacement pumps but instead have open, tapered channels. Their ability to generate high outlet pressures is due to drag flow, and is mainly

dependent upon screw geometry and the viscosity of the slurry being pumped.

The single screw extruder can be designed for multiple functions, such as melting, mixing, grinding, and high-pressure pumping. It can still maintain near-plug flow and low residence time (low volume in process) while accomplishing the above functions.

A short description of the extruder characteristics and its applicability to the proposed project is in order. The extruder has the capability to pump very viscous materials and at the same time heat the material to the desired temperatures. The higher the viscosity, the more viscous dissipation is obtained through internal heating caused by the mechanical friction. Additional heat is added through the wall of the extruder barrel. An extruder schematic is shown in Fig. 1.

The classical use for the extruder is in polymer extrusion. The University of Arizona has used extruders extensively over the past 30 years not only for plastics but also in a biomass liquefaction plant, where highly concentrated cellulosic slurries were pumped into a reactor operating at 3,000 psi and around 400C (White et al., 1989). The near-plug flow condition in the extruder and its good mixing capabilities have already been determined analytically and experimentally (18,21). The recirculation flow and the high shear between the flights and the barrel which are tightly fitted are the main factors in the good mixing occurring in the extruder and for the homogeneous product obtained. Also, the channel depths in the mixing section are small, usually less than one inch, which also assists in developing high shear rates for good mixing. The start-ups and shut downs are very simple and easy and it is also easy to exchange the small amount of hold-up with inert material wherever necessary.

Fig. 1

Basic Plasticating Extruder Concept

An extruder consists of a helical screw that conveys material through a barrel and towards a die. The depth of the screw channel decreases from the feed section to the mixing section to compress the material. Details on extrusion theory and extruder performance can be found elsewhere. (14,18). Solid materials in the form of powders, pellets, flakes, beads, granular regrind, and highly-concentrated liquids or slurries may be fed to the extruder. The material is subjected to the necessary heating or cooling and develops sufficient pressure to force the viscous material through the die at the desired flow rate.

The helical geometry of the screw results in a "plug of solids" moving down the channel, and the flow pattern is composed of axial and tangential components which can be expressed as a force balance and as a torque balance, respectively. It is the fact that the torque balance must be satisfied that the screw of the extruder is an efficient conveyor of solids. It has also been proven by Wolf and White (21) that near-plug flow exists in solid screw conveying units.

Plasticating Extruder Operating Correlations

The basic equation found in the literature for calculating the net flow rate is as follows:

Eq. 1

Where: Q = net flow rate, Qd = drag flow rate, Qp = pressure flow rate, Q1 = leakage flow rate, N = rotational speed of screw, DP = P2 - P1 = pressure drop, m = viscosity of melt, A = constant, B = constant, C = constant.

The transverse flow is not included in Eq. (1) since it does not contribute to the net flow output. For the very small flight clearances between the barrel and screw that normally exist in extruders or even for higher clearances developed due to wear and for the very high viscosities that we deal with in extrusion, leakage flow over the flights can be neglected in Eq. (1), (22).

The more fundamental equation for the melting section that neglects leakage flow and flight width but takes into account various screw parameters and operational conditions is:

Eq. 2

Where: Vbz = pDNcosq, W = Dcosq, DZ = L/sinq, L = /n, = length of screw, M = number of flights, D = barrel diameter, H = depth of channel, q = helix angle, Fd = drag coefficient, Fp = pressure coefficient.

To obtain the pressure flow term in Eq. (2) it is necessary to know the pressure drop across the metering section and the viscosity of the melt. The viscosity is a function of both shear rate and temperature and it must, therefore, be determined for each experimental condition separately. For the extruder, the shear rate is obtained from:

Eq. 3

From the shear stress versus shear rate plots for several temperatures, the apparent viscosities are calculated and plotted versus shear rate for constant temperature or versus temperature for a series of thermoplastic materials that has been compiled.

The Proposed Vitrification Process

The proposed process and operation for high level nuclear waste vitrification would use an extruder-melter instead of the glass melter. An extruder 4-5 ft. long and with a screw diameter of about 2.5 inches is already considered a commercial unit. The hold-up of such an extruder would be around one liter. One could consider several extruders in tandem or a single long extruder with several sections.

The input to the first stage could be a sludge or a very concentrated solution of the high level radioactive waste and the other components for the glass. This unit would operate at a temperature of above 100C, thus causing the water and other volatile compounds to evaporate. Another stage would operate at temperatures of above 500C and could be used for the decomposition of nitrates, carbonates and other decomposable materials. The separation of the water vapor from the other gases would reduce corrosion problems. Yet another stage would operate at about 900C for the final stage of glassification. The correct temperature range will be determined so as to achieve pumpability and good mixing of the glass in the extruder-melter. The important point is that an extruder can pump slurries and achieve good mixing at much higher viscosities (and hence lower temperatures) than other mixing devices. An extruder canalso develop high pressures as needed for the pumping of the glass into the canisters reducing Cs2O evaporation and reducing the release of other gases that may be formed from the system.

The potential advantages of this extruder-melter vitrification method of particular interest are:

1. The low holdup or high throughput:
 a. Reduces the size of the glass-melter.
 b. The start-up and shut-down times are short due to the low hold-up of the extruder-melter.
 c. The low material hold-up of the extruder-melter would simplify disposal problems in the event of a failure.

2. The operating temperature for the glass formation would be lower since there is mechanical mixing in the extruder-melter and higher viscosities could be permissible, unlike in the Joule-heated glass melter, where high temperatures are needed to enhance mixing by melt convection. These lower temperatures are beneficial from the corrosion and the energy points of view and for reducing the vapor pressure of volatiles.
3. The high pressure in the extruder-melter would reduce the evaporation of the Cs2O and keep it in the melt. Also, a recycle line is envisaged between the outlet of the extruder-melter and the lower pressure inlet of the feed material, thus eliminating the possibility of escape of Cs2O.
4. Less corrosive gases will be produced since H2O, and NO2, will be drawn off separately.
5. Due to the plug flow characteristics of the extruder-melter and the good mixing due to high shear, recirculation flow and leakage flow between flights of the screw, the product will be well mixed and homogeneous.
6. No problems related to idling would exist in this type of unit operation. In fact a starved extruder-melter would be essentially empty of material. Thus, no problem of refractory metal particles or noble metal precipitates which accumulate in the conventional melter would exist in an extruder-melter (1).
7. The costs of investment and maintenance should be significantly lower.
8. The decontamination process will be simpler due to the small hold-up of the unit operation and its plug flow characteristics that would enable simple flash out of the system by non-radioactive material. In fact, with a starved extruder the hold-up is practically zero.

Details on the Model Glass

In order to test the ideas presented in this paper for the vitrification of high-level nuclear waste by the extruder-melter type process, one could use boric acid (H3BO3) as a model glass. This compound has viscosities similar to that of glass compositions but at lower temperatures and therefore can simulate all three stages needed in the real vitrification process namely dehydration (evaporation, drying), decomposition (calcination), melting, and off-gas treatment. This compound decomposes in two steps:

1. H3BO3 ---> HBO2 + H2O (at 190C)(12)
2. 2HBO2 ---> B203 + H2O (240C) (13)

The viscosity of the B203 depends on the temperature as given in the following table (15,19):

Table I

A sludge of H3BO3 as feed in the first step at temperatures above 100C, could be used to simulate the evaporation of water. Then, obtain the second step at temperatures of above 190C that would involve the decomposition of the boric acid to boron oxide and then produce glass with the following viscosities: 108.6 Poise at 350C; 107 Poise at 400C; 106 Poise at 420C. These viscosities are in the range of the viscosities of the borosilicate glass in the range of 550C-700C. In this simulation process we would expel gases in the form of H2O vapor in the first two steps of evaporation and decomposition, similar to expelling H2O and NO2 in the real vitrification process.

Materials of Construction for Extruder-Melters

Extruders to be considered for use in vitrification must be operating at high temperatures. Such extruders would need special metals to accommodate the strength and corrosion resistance needed at these high

temperatures. However, with the advancement in the development of special alloys for gas turbines, it is practical to select metal alloys which could provide the strength, corrosion resistance and thermal expansion limits required. Metals of the molybdenum alloy class could be one appropriate choice for this purpose. Also Inconel 690 is used at very high temperatures and could possibly be a candidate for the construction of the extruder-melter.

CONCLUSIONS

The scope of this paper was to present the concept of applying an extruder-melter for the high level nuclear waste vitrification process which could replace the presently used glass melter. Experimental work suggested in order to prove this concept would first include the vitrification of a model compound suitable to be operated at low temperatures in the 500C range. The low temperature operation would enable the use of presently available plasticating extruders. The test would prove the operability of the extruder melter in the three major steps involved, i.e. a) evaporation, b) decomposition, and melting. The next stage would be the development of an extruder-melter that is able to operate at around 900C. After such an extruder-melter is developed, non-radioactive elements that would simulate the real nuclear waste should be tested in the 900C range. Operability and homogeneity should be established. When this experimental work is successfully completed the proof of concept is achieved. For optimal design of the extruder-melter, theoretical analysis should be made in parallel to the experimental work.

ABSTRACT

Because of the issues related to disposal cost, long-term safety, environmental regulations, and public perceptions of risk from disposal, new treatment technologies are needed for processing of radioactive, hazardous, and mixed wastes. In this paper, three such technologies are briefly reviewed. These technologies are being applied at the waste processing facility of Scientific Ecology Group Inc., located in Oak Ridge, TN. The Quantum-CEP, a proprietary technology of Molten Metal Technologies Inc., is an innovative technology that will permit the effective processing of higher activity wastes such as the resins from nuclear power plants.

DRIVERS FOR NEW TECHNOLOGIES

New technologies are needed for processing of radioactive and hazardous wastes because of a number of factors. The primary drivers include:

1. Escalating disposal cost;
2. More stringent regulations and the need for environmentally stable waste forms;
3. Difficulties in dealing with mixed waste; and
4. Public perception of risk.

The uncertainty of access to a disposal site is a major concern of the generators of radioactive, hazardous, and mixed wastes. The Barnwell disposal facility that accepted most of the country's commercial low level radioactive waste closed to generators outside their compact in January 1995. Even though, the facility started accepting waste again in mid-1995, the uncertainty of access to a disposal site became very clear to many nuclear utilities. The state compacts that are responsible for developing low level radioactive waste disposal facilities are not making sufficient progress. After 15 years, most programs are stalled by cumbersome siting issues and public opposition to the development of new disposal facilities. No new disposal sites are expected to open any time soon, and it is now evident that disposal facility development is more complex, time-consuming, and controversial than originally anticipated. The disposal of high level radioactive waste and spent nuclear fuel awaits the opening of a federal facility at Yucca Mountain in Nevada, which may be two or more decades away. In the meantime, the spent fuel sits in wet or dry storage and high level waste is stored at Department of Energy's (DOE) tank storage facilities at Hanford and Savannah River sites.

The U.S. nuclear power industry, with 112 operating reactors, generates about half of the low level radioactive waste (LLW) shipped to commercial disposal sites and faces uncertain access to waste disposal sites and escalating waste management costs. The other small producers of LLW - industries, government (except the defense related research and production waste), academic and medical institutions that account for the remaining half of the commercial LLW - face the same storage, disposal and cost uncertainties. The disposal cost for LLW has escalated from approximately $5/ft3 in 1980 to over $300/ft3 today. Even the federal government (primarily DOE and DoD), which is by far the largest generator of radioactive and mixed wastes, faces new challenges in the areas of waste minimization, volume reduction, and waste stabilization. In a cost analysis report (1), Argonne National Laboratory has estimated that disposal costs for low level waste could range as high as $2,000/ft3 (all figures in 1994 dollars) depending on the disposal method. For hazardous waste the costs are specific to the contaminant. For example, for PCB's the costs can range from $950 to over $1,700/ton of incinerated PCB's in

a landfill operation. The mixed waste disposal cost can range to above $600/ ft3 .

For nuclear utilities, the disposal cost has become the primary driver for waste minimization and application of volume reduction technologies. During the last ten years, the volume of commercial LLW disposed of has decreased by two-thirds. In 1984, the total volume of waste disposed of was approximately 2,600,000 ft3 ; by 1993 it had declined to 790,000 ft3. However, the total activity of the waste disposed has tended to increase during that same period. The higher activity may be attributable to the increased age of several nuclear power plants and the need to replace equipment and components that have high activity levels.

The human health and safety criteria and the environmental protection standards have become more stringent. For radiation protection, the DOE uses a whole body dose of 100 mrem/y for the protection of an individual member of the public. Nuclear Regulatory Commission's 10 CFR 61 standard for the land disposal of low level radioactive waste uses a whole body dose criterion of 25 mrem/y. The Environmental Protection Agency's 10 CFR 191 specifies a criterion of 25 mrem/y whole body dose but it also specifies a groundwater protection criterion (from disposal activities) of 4 mrem/y. The MCL's specified for various hazardous contaminants are also stringent.

For mixed wastes, the regulatory issues have not been fully resolved and no facility in the country accepts mixed waste except the Envirocare site in Utah which currently accepts only certain types of mixed wastes where radioactivity is in the form of NORM or NARM materials.

The public apprehension about the risks of radioactive and hazardous wastes has meant longer and contentious siting processes for disposal facilities.

Above factors have led to a realization of the fact that treatment of wastes is a necessity for producers of radioactive and hazardous wastes. Above factors have also meant that innovative technologies for treatment of wastes are needed to save disposal costs and to produce environmentally stable waste forms that reduce the risks to human health and safety.

MAJOR ISSUES FOR THE UTILITIES

In a limited recent study, we looked at the waste treatment and management experiences at some representative utilities. These facilities included Duke Power Company's McGuire Plant, Boston Edison's Pilgrim Station, and Northern States Power's Monticello and Prairie Island Plants. The practices at these sites are generally representative of the nuclear utility industry. Most utilities do not find it cost-effective to invest in or operate major waste treatment systems for volume reduction or conditioning. Generally, utilities put more emphasis on waste source reduction through worker training, clean housekeeping, regular maintenance of active systems, and effective waste segregation. They may use limited waste processing on-site but for most part they use the services of contractors such as the Scientific Ecology Group Inc., (SEG) to volume reduce or condition their waste. The SEG has become the largest commercial waste treatment company in the country.

It has become clear that new methods are needed to process radiologically contaminated materials like resins, sludges, cartridge filters and EDTA solutions from nuclear power plants, and biological waste from hospitals and research establishments. Processing technologies such as dewatering and solidification do not volume reduce the resins and filters and do not

produce a waste form that can be safely stored for long period of time. Similarly, while incineration can reduce waste volumes significantly, the facilities employing incinerators were designed to handle activity <200 mR/h. The medium activity resins (1-10 R/h) can not be handled in such facilities. Resins are the second largest waste stream generated at nuclear power plants after the Dry Active Waste (DAW).

TECHNOLOGY DESCRIPTIONS

At the SEG facilities located in Oak Ridge,TN, a number of volume reduction technologies are being employed. For instance, the SEG ultracompactor has a force of ten million pounds and delivers the highest volume reduction factors possible for compactable waste even though the spring back characteristics of the waste will affect the ultimate volume reduction. In the past three years, SEG has identified three new technologies that will augment the existing technologies at its Central Volume Reduction Facility (CVRF) in Oak Ridge, TN. These new technologies are: Vitrification, Steam Reforming, and Quantum Catalytic Extraction Processing (Quantum- CEP). Most of the low level organic waste will continue to be processed via incineration. One of the three new technologies will be selectively applied to medium activity organic wastes or to the wastes that can not be incinerated. The targeted uses for these technologies are described below.

Vitrification: low level incinerator ash, glass, soil.
Steam Reforming: moderate activity waste, cartridge filters, sewage/sump sludges, EDTA/Decon solutions, hazardous waste, biological waste, paint/solvents, charcoal filters.
Quantum C.E.P. high activity waste, bead resins, powdered resins

A description of the new technologies and their application at the SEG facilities (2), along with a description of the incineration technology (because it is still one of the widely applicable technologies), follows.

Incineration

Incineration is the most economical and efficient technology for processing most of the low level organic materials like paper, plastic, wood, and rubber. It is also the most developed technology for a variety of uses and the designs on the market include: agitated hearth, controlled air, excess air cyclone, fluidized bed, rotary kiln and slagging pyrolysis, among others. Incineration provides a very high volume reduction, generally of the order of 100 : 1.

The first commercial incinerator for low level radioactive waste in the United States began operation in November 1989 at SEG facilities in Oak Ridge, TN. The system operates at temperatures up to 2,200oF which assures complete combustion of volatile materials. The incineration capacity of the system is 1,600 lbs/h. The emission control equipment consists of carefully chosen technologies consisting of a heat recovery boiler for off gas temperature control, a baghouse filter and a dual HEPA bank for particulate control, a wet scrubber for acid gas removal, and an exhaust reheat system for stack plume suppression. A second incinerator has been added at the CVRF in 1995. The combined incineration capacity at the CVRF is now approximately 14 million lbs per year.

Vitrification

As a subsidiary of Westinghouse, the SEG resources include the extensive experience of Westinghouse Nuclear Technology Group over the past 10 years. Vitrification experience includes design, fabrication, and operation of several different vitrification systems owned by SEG and for

other clients in U.S.A. and Japan. Vitrification systems are expensive to operate but they are well suited for processing of some organic wastes that are difficult to process. Contaminated soils and incinerator ash are prime candidate waste forms for vitrification. Since some generators are uncertain as to their ability to dispose of the incinerator ash, vitrification provides them the means to stabilize their waste into a final form that will be acceptable to all future disposal site operators. A 150 lb/h electric resistance heated vitrification system was installed at the CVRF in late 1994. This system is operational and is capable of vitrifying all the incinerator ash that results from the two large incinerators at the CVRF. Thus, the capacity for vitrification of 14 million lbs of DAW per year is in place at the facility. Sequential application of technologies - incineration followed by vitrification, makes it cost-effective for the processing of low level radioactive waste.

Steam Reforming

Steam Reforming is often called "Steam Detoxification" as it detoxifies or renders pathological or hazardous materials nonhazardous. Steam Reforming is a new thermal process where organic materials are decomposed. The process was originally intended for pathological wastes and hazardous wastes. A Steam Reforming system is generally a small closed loop system which produces a final waste form similar to incinerator ash. However, the processing methodology used is very different and the system is not classified by EPA as an incinerator. Unlike incinerators, Steam Reforming systems do not employ combustion in an oxygen atmosphere. Instead, the system employs steam reforming chemistry (at 600-2500oF), which volatilizes and reforms organics into CO, H2, CO2, H2O, and CH4.

Waste is charged into the system in a variety of ways, depending on the waste form. The aromatic organic wastes can be loaded into the system by loading the waste drum into the system autoclave, the Drum Feed Evaporator (DFE) unit. Higher throughput efficiency can be obtained when solvent or liquid organics deposited on solid materials are shredded and fed into the Waste Feed Evaporator (WFE). Liquid wastes can be flash atomized into the reaction vessel, which is generally a steel drum, inside the autoclave. Small containers, such as paint cans can simply be opened and placed on special rack inserts in the autoclave.

On startup, syngas and excess steam are injected into the evaporator to vaporize organic constituents which exhaust to a detoxification reactor in the main processing unit. At this location, the waste is mixed with excess steam and electrically heated to high temperature to complete the organic molecule destruction. The high temperature reforms the molecules into CO, H2, CO2, and H2O. This syngas then flows through a regenerative closed loop where various parameters of destruction efficiency are also monitored. The loop also contains a regenerative heat exchange train to allow cooling of the gas before it enters an absorber for halogen removal. After it exits the absorber, the gas is reheated and it is either recycled to the WFE or slipstream discharged to the off gas system. The discharge removes excess gas (water vapor and CO) and the radioactive gaseous and particulate activity through the HEPA filters. It is also possible to employ an optional catalytic converter upstream of the HEPA filters to oxidize CO to CO2.

The high temperature exothermic reaction destroys the hazardous and pathological wastes. Organic material is reduced to a small volume of ash

which is retained in the drum used to charge the waste into the system. This drum can later be supercompacted. Typical volume reduction as high as 100 : 1 can be obtained for some organic materials.

The closed loop system releases only water vapor and CO2; hence off gas treatment is generally not required for most type of organic wastes. Radioactive particles are collected in the HEPA filters. The Steam Detoxifier, the main processing unit, incorporates a high temperature reactor, heat exchanger, steam boiler, adsorber bed, HEPA filters, computerized process controller and extensive self monitoring equipment. System size is small, generally requiring less than 1000 ft3 of operating space. The remote operation and shielding of the system can be easily accommodated, thus permitting operation with higher activity waste. Since waste can be charged into the system in a closed drum and removed from the system after processing, still inside the closed drum, airborne contamination risks are minimized.

The SEG has a process which is licensed from the patent holder of the technology, Synthetica Technologies, Inc., of Richmond, CA. An extensive proof-of-concept testing on a variety of organic materials was conducted over the past year. The Synthetica Steam Detoxifier was found to be very effective in volume reducing many types of organic wastes including cartridge filters, sludges, EDTA solutions, paints and solvents, and other aqueous waste. It was also very effective in regenerating charcoal for reuse. Two steam reforming units are currently in place at the CVRF.

Quantum Catalytic Extraction Processing

Catalytic Extraction Processing (CEP) technology employs a bath of molten metal to render waste to its smallest elemental form. The process was developed (and patented) by Molten Metal Technologies Inc., (MMT) of Waltham, MA. Over 250 million dollars have been spent in the testing and refinement of this technology over the past five years to bring it to commercial markets. Even though it was originally intended for processing/destruction of hazardous and toxic wastes, it has emerged as an innovative technology of high potential for the processing of all types of wastes including radioactive and mixed wastes.

In 1993, a bench-scale test system was jointly constructed at CVRF by SEG and MMT. The purpose was to investigate the effectiveness of this new technology in processing radioactive waste, mixed waste, and specifically, the high activity organic resins. The test results led to a conclusion that a variation of the CEP, which incorporated radionuclide partitioning was the best choice for processing high activity organic resins. This new technique for processing radioactive materials is called Quantum-CEP.

Quantum-CEP molten metal bath operates at temperatures greater than 3,000oF. This allows significantly higher energy transfer to the waste material than the other thermal processing techniques such as incineration or vitrification. The process is coupled to a Catalytic Processing Unit (CPU) to destroy organic components of resins and control the partitioning of metallic ions (radionuclides) and chemical elements into three separate phases - gas, ceramic matrix, metal. This process effectively controls the deposition of many radionuclides, such as Cs-137, and chemical elements such as sulphur into preferred locations.

The resins are dried and injected into the CPU's molten metal bath which is contained in a disposable ceramic lined crucible. The metal bath, 1-2 ft3 in size, and operating at 3,500oF, instantly vaporizes organic resin and amalgams all metallic ions captured on resin into the molten metal.

The destruction process permits very high volume reductions of the complex organic materials placed in the molten metal bath as most of the material is converted into CO, H2, CO2, and H2O. For resins, volume reduction of 30:1 may be feasible, which is much higher than that obtained by the vitrification process. Quantum-CEP also produces a solid metal waste form which has superior strength and shielding characteristics as compared to the glass waste form produced by vitrification.

A 15 million dollar joint-venture (SEG and MMT) Quantum-CEP facility, designed to process 80,000 ft3 of resins each year is nearing operational stage in Oak Ridge, TN. This shielded facility will be able to process resins up to 10 R/h. These high activity resins are transported in High Integrity containers (HICs). Because of the high dose rate, all resin transfers and waste processing must be performed via remote handling equipment.

CONCLUSIONS

Three innovative technologies discussed in this paper can provide cost effective waste processing techniques for radioactive, hazardous, and mixed wastes. All three are commercially viable and available for application. For medium activity wastes, such as the resins from nuclear power plants, Quantum-CEP technology can provide a cost-effective processing technique, while also producing an environmentally stable final waste form. It is expected that it will permit processing and disposal of the resins at a cost significantly less than the current Barnwell disposal charges of $500/ft3 for medium activity wastes.

L-1

1946-1996 FIFTY YEARS OF "CIVILIAN CONTROL"

Presented at WM'96 Lunch

Roy G. Post
WM Symposia, Inc.

How many of you have been a part of the nuclear community for ten years?, 20? 30? 40? 50? Longer? I started in the West Stands at the University of Chicago 52 years ago this past January. Let's jump back to the birthing of the nuclear age begining with the first controlled nuclear chain reaction in December 1942. This was just 13 months prior to my introduction to the project.

December 1942 - the first controlled chain reaction, power in milliwatts - graphite moderated, no cooling. It became known as CP 1, Critical Pile 1. Security concerns were extreme:

An example: Fermi and the other nuclear scientists knew that only graphite and heavy water were sufficiently efficient as neutron moderators to permit a chain reaction with natural uranium. The best graphite we could buy absorbed too many neutrons. We couldn't tell the vendor what the contaminants were, just that greater purity was required. Even though the scientists did know the offending elements, they couldn't

tell the vendor because it could reveal that there were concerns about neutron absorbers, which in turn could mean we were working with something nuclear.
From the auspicious beginning of that first pile, these milestones, the foundation of the nuclear age was formed in only 30 months.
Development of nuclear reactor theory - including the four factor formula.
The scientists measured critical nuclear parameters - rumor had it that the Germans had made a serious error in measuring the diffusion length of neutrons in graphite. If this were true, it could have led them down the wrong path.
Critical Pile 1 (CP 1) was designed and built. Data were collected in order to
Design and build the Oak Ridge gas cooled graphite moderated reactor. This reactor was operated to make plutonium in gram quantities.
The plutonium was used to develop the chemical process to separate, purify and reduce plutonium.
Metallic plutonium was made so we could measure its chemical and physical properties. When our measurements couldn't be confirmed we would submit that plutonium was such a new element it hadn't settled its properties.
With the data from the operating reactors, Dupont engineers designed and built the Hanford reactor systems. These were chemical and mechanical engineers with no nuclear background or experience. Obviously, no one had any nuclear experience we had to learn as we went. We enjoyed great communication between the engineers and the scientists. My first discussion of my work was to an audience of about thirty which included three Nobel Laurets,
you guys today are a pushover.
The Hanford reactors generated a million kilowatts each with fuel carrying heat loads that would melt them in seconds without water cooling.
Not only the four reactors, but fuel manufacturing plants and fuel processing plantswere built, tested and operated long enough to make, separate, purify and reduce kilograms of plutonium.
Ten to twelve major steps were begun and completed between the end of 1942 and the middle of 1945, only two and a half years from the first chain reaction.
Of course, we were highly focussed on the military job at hand. But we would, in lighter moments, let our imaginations dwell on the future, after the war when we would have the opportunities to develop this wonderful and powerful new nuclear energy. Soon, very soon, the war was over due in large part to the product of our efforts. Now, we thought, we could consider other problems and opportunities.
1946, what a year that was. Those of us working on the project were becoming more and more excited about the opportunities and the work to be done. We had a vision and a mission but we had no means to support our efforts. We needed a unique political action which would provide for the safe commercial development of peaceful benefits from nuclear energy. We could easily see ways to generate electrical energy. We knew how to use isotopes to measure processes. We knew that radiation could be used to enhance the properties of plastics, glasses and gems. We believed that we could pinpoint radiation sources in the body for diagnosis and treatment of a host of human and animal ailments..

1946, we were ready to move on, some of us returned to the Universities to teach or to pursue graduate studies. Many would rejoin the crusade later. Most of us we wanted to continue and explore the opportunities. It was a time of great expectations, unbridled enthusiasm and idealistic hopes. It was a year of great events for me too, Becky and I tied the knot and Ruth Jean was born into our little family.

I would like to share some of the euphoria and attitudes at that time, as I remember them. My viewpoint is that of a twenty three year old chemical engineer with only two years of research experience. After four years of war when almost all of our thoughts were concentrated on "winning the war", the prevailing mood, after the great victory, was to remove the war time controls so we could get on with our lives in peace.

There were three dominant concerns in the newly formed nuclear community to which I belonged.

First the benefits from the nuclear technology we were developing included a source of huge amounts of energy that would have immense potential benefit to the war-ravaged world. We also recognized that there were many uses for radioisotopes to be developed.

Second, with our years of indoctrination, we were convinced that the dangers of excessive exposure to radiation and spread of radioisotopes were real. Nonetheless, we also knew that the methods of detection were so sensitive and the biological effects so well understood that the public health could be well protected. We were concerned that the implementation of the necessary regulations were not in place. Proper radiation protection procedures would be required for all nuclear applications.

Third, we were concerned that proper legislation would be written to move control from the military to the civilian and to develop the great potential.

Let us reflect on our hopes for the legislation by considering the benefits, health physics concerns in detail and our standing with the political and social world in 1945 and 1946.

BENEFITS

As nuclear engineers, we were excited about participating in the development of a technology so powerful that it would change our world in ways we could not even imagine. In order to understand and explore the development of nuclear energy for civilian uses, instead of limiting it to weapons, we held meetings and had extended discussions of the possibilities. During this time almost all of the reactor types were conceived. These included the gas cooled, graphite moderated reactor, the pressurized water reactor, the boiling water reactor, the sodium cooled fast reactor and others that didn't make it, such as the molten salt reactor. Almost every combination of moderator, fuel and coolant was examined. The potential uses of isotopes in medicine, well logging, agriculture, plastics and other industrial processes were proposed and analyzed.

We felt secure and the future was bright. The US not only had the "bomb" but the only industrial complex untouched by the war. It seemed that the endless opportunities dwarfed the problems overall, and even more so for the budding nuclear community.

RADIATION CONCERNS

Before 1942, a few curies of radium were available. Now, the Hanford reactors were producing megacuries of radioisotopes. We were concerned that our proven methods of working safely with these dangers should be

followed. Data on the biological effects of radiation were available from those using x-rays, accelerators and radium. The research programs to develop designs for the Hanford reactors, the processes to separate plutonium and produce the metal had been paralleled with research programs studying the biochemistry of radioisotopes and their effects on living systems.

In the West Stands at the University of Chicago, goats were injected with various radioisotopes. Sometimes they would escape from their cages and come up the stairs to visit us while we were running solvent extraction columns on the graveyard shift. Seeing a goat, known to be radioactive, climbing the stairs to our operating position was an awakening experience. Nonetheless, it was proof of the active research program in the biological effects of radiation. Confinement of the goats was soon perfected.

At Oak Ridge and at Hanford, the research with laboratory animals, aquatic and terrestrial plants, and the soil was well financed and was carried out by the best scientists in the world.

The effects of radiation were correlated with the best estimates of the doses and dose rates from the time of the discovery of x-rays and radium to the beginning of the project. Based on these data, limits were set to assure that all those working with radiation received less than one tenth of the dose producing clinically observable effects.

You may not know that when the medical use of x-rays became widespread, but before the dangers of high exposures were recognized, you could identify a pediatrician by the radiation damage to his hands and arms such as scarring and loss of fingers from holding infants in x-ray beams. The lessons were learned so that now, fifty years later, no clinically observable health effects have been found at or below the levels established in the early forties.

From the very beginning, research programs, safety procedures and extensive biological testing of those of us working with high levels of radioisotopes was a standard daily routine.

Back in the early 40's, there was the almost paranoic concern at Stagg Field and throughout the project that the nuclear work might be discovered. In spite of that, the concern for the public safety outweighed the security concerns and when the rods were pulled for that first chain reaction, a technician was stationed outside of Stagg Field's West Stands to measure radiation levels and protect anyone that might be passing on the sidewalk.

One of the first actions the new nuclear community took which showed their public concern was to eliminate the use of x-rays to fit shoes. I was not aware of any widespread health effects from the foot x-rays but we knew that they were many times higher than we would permit in our work. We also promoted the monitoring and regular calibration of medical and industrial x-ray machines.

We recognized and understood the hazards of nuclear radiation. We had developed the knowledge to control it and had assumed the responsibility to do so.

LEGISLATION

Nonetheless, we were determined to do all we could to avoid irresponsible exploitation of nuclear energy that could result in wide spread radioactive contamination. We also believed that every effort should be extended to prevent the proliferation of nuclear weapons. The scientists and engineers engaged in this work agreed that legislation was needed to

assure the public health, to promote the development of this technology and to keep it from those that would miss use it. Looking back, I don't know how much we influenced the Congress at that time, I expect more than any of us here do now, but the results were what we thought they should be. Looking back from today's perspective, we might want things to be somewhat different.

The first attempt at enabling legislation was the May-Johnson bill which failed because of concern that the military would retain too much control. Senator Brien McMahon ofConnecticut introduced a compromise bill which established the United States Atomic Energy Commission with five civilian members, a general advisory committee and a military liaison committee. This, the most important single piece legislation in the development and use of nuclear energy, was enacted into law August 1, 1946. This act recognized and confirmed the responsibility of the United States not only to develop nuclear energy for the general benefit but to regulate its use to protect the health of all the people. Thus began many decades of cooperation among the Congress, through the Joint Committee on Atomic Energy, the Atomic Energy Commission and the people of the United States.

There were some interesting aspects in the law many which have now been changed. For example, mining of uranium was excluded from the AEC control, hence there was no federal responsibility for the control of mill tailings. There have been modifications of this law and its basic structure was discarded in 1974.

The McMahon Act emphasized the concerns of the nuclear community for the public health. Standards to limit exposure were extremely conservative for those working in the field and they were reduced by a factor of ten for the general public. This may have been a disservice, in that even these levels were much lower than those required for safety, and now, they have been reduced even further. Often the reduction is made only because the lower levels were readily measured and procedures could be easily developed and used without high costs. No one anticipated the costs of lost electrical production and costs from extending construction schedules to implement lower limits and the hearings held in response to public reactions to a perceived need to meet such low levels.

From the end of WW II until Rachel Carson's "The Silent Spring", which did not address nuclear radiation, nuclear operations were considered to be well within politically and socially acceptable standards or values. Almost all of the public recognized the benefits of nuclear energy and had confidence in the competence and responsibility of the nuclear community. It's a bitter irony is that this was lost, not through failure to live up to promised performance, but to a revolutionary change in political views, social values and expectations.

After these fifty years since the McMahon Act became law, I have seen nothing that would change my belief that nuclear technologies still offer the best promise for the energy needed to bring all nations to acceptable levels of living. Since nuclear reactors generate no carbon dioxide, sulfur dioxide or nitrogen oxides, displacing fossil fuel electrical generating plants will actually decrease carbon dioxide, sulfur and other pollutant emissions and improve the atmosphere we breath. More available electrical energy, produced by nuclear reactors can promote the economies of many of the less privileged peoples and begin to stabilize the relations among nations. People that are well fed and secure don't start wars and breed terrorism.

FIELD AND LABORATORY TESTING OF SEAL MATERIALS PROPOSED FOR THE WASTE ISOLATION PILOT PLANT

M. K. Knowles
Sandia National Laboratory
Repository Isolation Systems Department
Albuquerque, NM 87185

C. L. Howard
RE/SPEC, Inc.
Carlsbad, NM 88220

ABSTRACT

The Small Scale Seal Performance Tests (SSSPT) were a series of in situ tests designed to evaluate the feasibility of various materials for sealing purposes. Testing was initiated in 1985 and concluded in 1995. Materials selected for the SSSPT included salt-saturated concrete, a 50%/50% mixture of crushed salt and bentonite, bentonite, and crushed salt. This paper presents a summary of the SSSPT field program, results of the in situ testing, and a discussion of post-testing laboratory studies of salt-saturated concrete. Results of the SSSPT support the use of salt-saturated concrete, compacted bentonite clay, and compacted crushed salt as sealing materials for the WIPP.

BACKGROUND

The Waste Isolation Pilot Plant (WIPP), located in southeastern New Mexico, is being developed by the U. S. Department of Energy (DOE) as a potential disposal site for transuranic wastes. The disposal site is located approximately 650 meters below ground surface and consists of a repository mined in a bedded salt deposit. Disposal of wastes in salt is considered advantageous because over time the salt will creep, closing around the waste and thereby encapsulating and isolating hazardous constituents from the accessible environment. Prior to certification as a disposal site and initiation of disposal activities, the DOE must demonstrate that the WIPP will meet all regulatory requirements. As part of this demonstration, Sandia National Laboratories (SNL) is working with the DOE to develop a sealing system design for the four shafts that provide access to the repository.

This paper discusses the Small Scale Seal Performance Tests (SSSPTs), a series of in situ tests designed by SNL and conducted by SNL and Westinghouse Electric Corporation, Waste Isolation Division to evaluate the feasibility of various materials for sealing purposes. The discussion is focused on the results of the field program, with a brief summary of the post-test laboratory analysis of concrete seal materials. The positive results of the SSSPTs support the inclusion of salt-saturated concrete, compacted crushed salt, and compacted bentonite clay in the current WIPP shaft sealing system design.

The system design (1) is based on the use of effective seal materials and the reduction of uncertainty through functional redundancy. Seal components must maintain structural integrity and act as barriers to fluid flow throughout their design life. Redundancy is obtained through the use of multiple components and materials. Salt-saturated concrete,

asphalt, and compacted bentonite clay components will serve as barriers to fluid flow for several hundred years following shaft seal construction, allowing time for the primary long-term crushed salt seal to become fully effective. Crushed salt and compacted bentonite clay materials comprise the long-term components for the shaft seal system. These components are expected to remain functional for thousands of years. A conceptualization of the proposed WIPP shaft sealing system design is depicted in Fig. 1.

Fig. 1

SMALL SCALE SEAL PERFORMANCE TESTS: PROGRAM GOALS AND DESCRIPTION

To assess the performance of candidate seal materials in situ, the SSSPTs were initiated several years before the current WIPP sealing system design. Five series of tests were conducted on seals up to 1m in diameter. Essential SSSPT goals were to 1) use seal emplacement technologies that are compatible with standard industrial practices, 2) demonstrate reduction in fluid flows, and 3) verify that seal components remain structurally sound. Test results were used to evaluate materials in terms of the sealing program goals. The small scale of the field tests (hence the name) allowed performance of numerous tests under a range of conditions and configurations.

A series of five SSSPT tests (A-D and F) was initiated in 1985 under the guidance of the original Test Plan. Series F consisted of a grating demonstration and is not discussed in this paper. (The fourth test was later expanded into two phases.) Details on the development, construction, and proposed testing sequence for each series were documented as addenda to the original Test Plan. Each test series evaluated a different seal material and/or seal configuration. Seal materials were emplaced in either horizontal or vertical boreholes at the repository horizon. Figure 2 presents a schematic of a typical SSSPT for the emplacement borehole, seal structure, and fluid flow test apparatus configuration. Many of the emplaced seals were equipped with internal stress and strain gages.

Fig. 2

Table I lists the seal material, configurations, and construction dates of SSSPT Series A-D. A brief description of the seal materials is presented in Table II.

Table I

Table II

The SSSPT field program verified that the candidate materials could be emplaced using standard industrial equipment and practices. The in situ fluid flow and structural behavior of the seal materials were also assessed. In addition to the field test program, samples from a salt-saturated concrete seal (emplaced in 1985) and the surrounding host rock were extracted from the field configuration for laboratory analysis in 1994. The analysis included visual observation of the seal/rock interface, quantitative evaluation of the gas permeability of the seal material, and petrographic analysis of the seal material and the surrounding host rock.

EMPLACEMENT TECHNIQUES

A primary goal of the SSSPT program was to use or adapt existing technology to the construction of repository seals. Methods used to construct seals for SSSPT Series A-D were all direct applications of widely used construction practices. Emplacement configurations for each series are summarized.

Test Series A consisted of concrete seals emplaced in vertical-down boreholes. Salt-saturated concrete was emplaced in selected seal intervals using gravity flow. No forms were used. In some cases, vibration was used to promote even concrete distribution around structural performance gages (2).

Series B seals were also comprised of concrete, but were emplaced to plug horizontal boreholes. Construction of these seals employed a small pump to fill pre-formed intervals with concrete. Vibration was not applied (3).

Series C seals consisted of precompacted salt and salt/bentonite block structures that were constructed to plug horizontal boreholes. One-meter intervals of the round boreholes were enlarged to create square chambers into which the blocks were emplaced. The blocks were manufactured using a modified pressed-earth adobe block machine and emplaced to form a seal structure with minimal void spaces. No mortar was used between blocks (4).

Series D seals were also constructed of precompacted salt, salt/bentonite, and pure bentonite blocks, but the seal structures were built to plug vertical-down boreholes. Phase 1 seals consisted of salt blocks. Phase 2 seals consisted of a 100% bentonite core with layers of 50%/50% crushed salt/bentonite and/or 100% crushed salt above and below the core. Emplacement techniques were essentially the same as for Series C except that blocks were trimmed to conform to the cylindrical geometry. Portions of blocks were excavated as necessary to accommodate gages placed for monitoring structural performance (5). In some cases, crushed salt was compacted directly into the seal interval using a hand-operated tamper to achieve densities approximating those achieved using precompacted blocks.

FLUID FLOW PERFORMANCE

Seal system permeabilities for the SSSPTs, derived from a series of in situ fluid flow measurements, are presented in Table III. The concrete seals have been subjected to the most extensive fluid testing program. All seals were either gas- or brine-flow tested immediately following seal construction in 1985 to 1987, and a selected subset was retested from 1993 to mid-1995. Fluid injection pressures of up to 2.3 MPa were used in the field testing program. Tracer-gas testing, constant-pressure gas- and brine-flow testing, and constant-volume brine-flow testing were conducted on the concrete seal systems. The seal system consists of the seal material, the seal/host rock interface, the zone of rock immediately surrounding the seal, and the far-field host rock. These tests do not provide information regarding the flow paths of the test fluid. Therefore, the calculated system permeability represents a composite fluid barrier presented by the seal system. From an engineering perspective, these tests provide an excellent means for evaluating the entire seal system.

Table III

Seal system permeabilities for the concrete SSSPT were derived through numerical computer simulations of brine- and gas-flow behavior. Fluid injection was simulated for a conceptualized model of the seal system. Estimated ranges for the formation and seal permeabilities, formation storativity, and seal porosity were used to generate pressure-decay and mass-flow-rate curves. The generated curves were then compared to the field data. Hundreds of computer simulations were used in the analysis, and a best fit to the field data was obtained using an optimization

routine. This technique produced a best estimate of the permeability for each seal system. Details of the analysis tool and conceptual model may be found in Pickens et al. (6) and Beauheim et al. (7).

To improve confidence in the data interpretation, additional testing was conducted to characterize the actual flow paths. Several boreholes were drilled in the formation surrounding a Series A seal. Gas flow testing was conducted in these boreholes to assess the extent and permeability of the disturbed rock zone in the test area. The permeability of the disturbed zone was found to be approximately 10-20 m2, which was consistent with the permeability of the complete seal system.

Brine flow testing was conducted on 50%/50% crushed salt/bentonite seals. A high rate of brine injection led to failure of the first seal, so the brine injection rate was reduced for the second and third test sequences. An average pressure differential of less than 0.013 MPa was maintained throughout the testing period. The steady-state flow rate of brine into the test interval was monitored for approximately 800 days. Brine that seeped through the front of the seal was recirculated during this period (8). Assuming that all flow occurred through the seal and that one-dimensional Darcy flow approximations are valid, the permeability of the 50%/50% salt/bentonite seal material was derived from Darcy's Law. Attempts to conduct gas flow testing were unsuccessful because of a small separation at the seal/host rock interface. The brine permeability of the 50%/50% salt/bentonite seal material was two orders of magnitude higher than laboratory values of similar materials.

The crushed salt seals constructed for Series D, Phase 1 were not expected to present a barrier to flow until the salt had reconsolidated to at least 90% of the density of intact halite. At the time of test termination in mid-1995, the seal material was determined to have a porosity of at least 12% (i.e., a fractional density of 88% of the density of intact halite compared to 82% at the start of the test). Attempts to develop gas pressure in the seal test interval confirmed that the permeability of the crushed salt was too high to constitute an effective fluid barrier. This finding was consistent with the expected behavior of reconsolidating crushed salt.

Brine injection testing was conducted on the two vertically emplaced bentonite core seals. Testing was initiated in 1990 for one seal and in 1994 for the second seal. Throughout the testing period, the pressure differentials across the seals were maintained at approximately 0.72 and 0.32 MPa, respectively. During the test period, no brine was observed at the top of either seal. A conservative estimate for the seal system permeability was made by assuming that 1) the seal material was saturated; 2) test conditions were at steady state; 3) all flow was into the seal material; and 4) formation brine contributions were negligible. The permeability was then derived from Darcy's Law in a manner similar to that used for the 50%/50% crushed salt/bentonite seals, and is listed in Table III.

Gas flow testing was conducted on one of the bentonite core seals to evaluate the gas threshold pressure of the seal material. The test interval was pressurized in 0.67-MPa intervals. After each increase in pressure, the interval was shut in to allow the system to come to equilibrium. As shown in Fig. 3, the seal exhibited negligible gas flow until the test interval pressure exceeded 4 MPa. This test was conducted to provide qualitative information on the behavior of bentonite seals subjected to high gas pressure.

Fig. 3.

STRUCTURAL PERFORMANCE

Many of the SSSPTs were equipped with internal stress and strain gages. Measurements taken from these gages were used to monitor the seal structural performance. Structural failure of a seal material would be detected through seal stress- and strain-state monitoring, fluid flow measurements, and visual observation. The creep behavior of the host rock would also influence the structural response of a seal material. Quantification of the salt creep was derived from borehole closure measurements, which were made in both open and closed boreholes. Gage type, orientation, and location are specified in the applicable test plan addendum. A representative sampling of the SSSPT gage data is presented here.

The structural response of the concrete seals can be evaluated from inspection of radial and circumferential strain (Fig. 4 and 5), radial stress (Fig. 6), and borehole closure measurements (Fig. 7). The general strain gage trend depicts a compressive strain rate that was relatively rapid after seal emplacement but that monotonically decayed with time and continued to increase, but at ever slower rates. This behavior reflects the concrete strains under the compressive loading applied by the surrounding salt. The stress gage data showed that seal compressive stresses rose rapidly immediately following seal construction, attaining steady-state after 100 to 200 days. Creep closure of the borehole was inhibited by the presence of the concrete seal, as illustrated in Fig. 7.

Fig. 4

Fig. 5

Fig. 6

Fig. 7

Visual observations of the concrete seals revealed no spalling or other external evidence of structural degradation. The relatively smooth trend of stress and strain gage data, coupled with the results of fluid flow testing, visual observations, and laboratory analysis (presented in the next section) corroborate the conclusion that the salt-saturated concrete maintained structural integrity throughout the testing period. The unconfined compressive strength of the salt-saturated concrete exceeds predicted formation in situ stresses by more than a factor of three (9). The constitutive model for reconsolidation of crushed salt (10) predicts very little resistance to porosity reduction for porosities greater than 10%. Borehole closure measurements from the 100% crushed salt seals (Fig. 8) support this prediction. These seals were emplaced with an initial porosity of approximately 18%. Seven years later, closure measurements indicate that the porosity may have been reduced to approximately 12%. These internal closure measurements differ only slightly from closure in an empty borehole. Measures of stresses internal to these seals are nominally between 0.1 and 0.2 MPa, as shown in Fig. 9. This finding is also consistent with model predictions that the crushed salt will offer little resistance to closure when the material porosity is greater than 10%.

Fig. 8

Fig. 9

Nominal internal stresses for the 100% bentonite core seals are shown in Figs. 10 and 11. The increasing trend shown in Fig. 10 could be the result of compression resulting from borehole closure, bentonite swell pressure, or a combination of the two processes. The reduction in stress

at approximately 1400 days, shown in Fig. 11, may be related to ion-exchange with permeant brines in the bentonite fabric. These issues are currently being addressed by a separate laboratory program.

Fig. 10

Fig. 11

Structural performance data (as derived from stress, strain, and borehole closure data) were consistent with current understanding and expectations of the respective seal materials. To the extent necessary for demonstrating sealing design adequacy, these data will be incorporated into the material models used to evaluate the shaft sealing design.

LABORATORY TESTING OF SSSPT CONCRETE

In late 1994, approximately nine years following construction of the vertically-emplaced concrete seals, a "post-mortem" analysis of the sealing system was conducted. Cores of intact host rock and samples of the concrete seal material and seal/host rock interface were extracted from the test region. Petrographic studies of the phase assemblages of the concrete seal material and the microstructure of the intact rock were conducted. Gas permeability testing was conducted on concrete core samples.

Preliminary results of the laboratory tests indicate that, although the concrete seal was exposed to native brines during the testing period, the material experienced no deterioration in performance capabilities. Phase assemblage analysis of the concrete showed minimal degradation of the seal material. This result is consistent with a more extensive analysis of concrete specimens extracted from the WIPP underground in 1991 (11). The gas permeability of the concrete core samples was found to be approximately 10-20 m2, which is consistent with the field measurements. The seal/host rock interface was visually inspected for signs of brine migration and deterioration along the interface zone. No signs of degradation or separation were found. In addition to visual inspection of the interface, field observations of the retrieval were recorded. During extraction of the seal/host rock interface material, breakage occurred preferentially through the seal material rather than along the interface. This observation was consistent with direct shear testing of concrete specimens extracted from the WIPP underground in 1991 (12).

Microstructural analysis of the intact rock showed dilation along the salt grain boundaries for specimens taken from the immediate vicinity of an open borehole. Specimens taken in the immediate vicinity of the concrete seal, as well as those from a far-field location, showed no dilation. The calculated gas permeability for these regions also showed that, in the immediate vicinity of the concrete seal, a disturbed zone did not exist. The absence of a disturbed zone in this vicinity indicates that either the seal prevented the formation of a disturbed zone or that, through the process of creep closure, any disturbed rock zone that had formed around the seal was subsequently eliminated. The post-mortem testing sequence provided additional confidence in the ability of salt-saturated concrete to retain fluid flow and structural performance capabilities in WIPP salt.

SUMMARY AND CONCLUSIONS

The goals of the SSSPT series to use standard industrial practices for seal emplacement and to evaluate seal materials for their ability to retard fluid migration and remain structurally sound were met. No new technologies were developed for the emplacement of the SSSPTs. Fluid flow testing of the sealing systems provided strong evidence that both salt-

saturated concrete and bentonite would function effectively as barriers to fluid flow. The testing also supported model predictions of the behavior of a crushed salt seal and resulted in elimination of 50%/50% crushed salt/bentonite as a viable seal material. Stress, strain, and borehole closure data, when coupled to visual observations and fluid flow test results, demonstrated that all seal materials maintained structural integrity throughout the testing period. A post-mortem analysis of the concrete sealing system provided additional confidence in the ability of this material to function effectively at the WIPP horizon.

EFFECTS OF A HYPOTHETICAL WATER INGRESS INTO A SALT DOME REPOSITORY ON THE ALUMINUM CLADDING OF DIRECTLY STORED MATERIAL

TEST REACTOR FUEL ELEMENTS

J. Fachinger
I. Syuhada
H. Rainer
Forschungszentrum Karlsruhe GmbH

ABSTRACT

The direct final disposal of spent material test reactor fuel elements (MTR-FE) is being discussed in the Federal Republic of Germany as an alternative to reprocessing (1). A possible repository under consideration is a salt mine and the accident scenario for long-term safety analysis is a hypothetical water ingress.

A water ingress involves the formation of highly concentrated brines which first come into contact with the storage casks. The cask design ensures a lifetime of 500 years in Q brine.

After this period, the brine may penetrate into the cask and act on the MTR-FE so that a radionuclide release would be conceivable.

It is therefore of interest to know whether the MTR fuel element cladding materials (high-purity aluminum, AlMg1 and AlMg2) have a barrier function with respect to radionuclide release when exposed to highly concentrated brines. Relevant corrosion experiments have been carried out at the Institute for Safety Research and Reactor Technology of KFA Jlich (2). In a first test series, the above materials were exposed to differently concentrated repository-relevant brines. Interesting correlations were found, in particular, by varying the test temperature and adding different metallic alloys. The results were incorporated into mass loss calculations in order to obtain a first picture of the corrosion behavior involved.

Furthermore, electrochemical studies were carried out providing an insight into the mechanical processes of corrosion.

On the basis of these studies, it may be concluded even at this stage that the cladding materials of high-purity aluminum, AlMg1 and AlMg2 do not exercise a barrier function for radionuclide release. Further investigations on the release of radionuclides from spent fuel element sections in brines will serve to determine the source term for release calculations.

INTRODUCTION

After a decision has been made against the construction of a German reprocessing plant, the direct final disposal of spent fuel elements is being discussed in the Federal Republic of Germany as an alternative to reprocessing abroad. In order to protect man and nature from the harmful effects of radioactive waste, final disposal is to be effected in underground stable geological formations ensuring safe containment of the radionuclides involved. Possible repository formations are salt mines in northern Germany (Wendland), which have remained almost unchanged since their formation approx. 200 million years ago because they are isolated from water-bearing strata. Safety analyses for such repository formations have already been carried out for the emplacement of heat-generating waste from reprocessing, and they demonstrated the basic suitability of a salt mine for final disposal.In these long-term analyses, a water ingress into the repository was assumed as a hypothetical accident. Since spent fuel elements greatly differ in their chemical and physical properties from vitrified reprocessing waste, the effect of such an accident on the fuel elements must be examined. These investigations are being carried out at the Research Centre Karlsruhe for fuel elements from UO2 pellets

and at the Institute for Safety Research and Reactor Technology of KFA Jlich for fuel elements from research and high-temperature reactors. The experiments on the long-term safety of HTR-FE are nearly completed.

The problems of a direct final storage of spent fuel elements from material test reactors (MTR) have been dealt with since 1993. These fuel elements consist of a metallic uranium-aluminum alloy as the fuel kernel enveloped in aluminum. An ingress of water leads to the formation of highly concentrated extremely corrosive brines. The storage casks of the "Pollux" type are designed for a lifetime of 500 years in such brines. After this time, the brine may penetrate into the cask and act on the MTR fuel elements so that radionuclide release would be conceivable in the salt mine. Since the fuel kernel is enclosed in an aluminum cladding, the question arises whether this cladding has a barrier function with respect to release. In a first investigation series, the corrosion of aluminum was therefore studied under repository-relevant conditions.

EXPERIMENTAL

The chemicals used in the present study were of analytical-grade quality. The following equipment was used for the determination of mass loss:

drying cupboard from Heraeus

ultrasonic cleaning device from Bandelin GmbH & Co, Berlin

The following equipment was used for electrochemical work:

recorder "DIGICASS 600" from Laumann, Selb

potentiostat, Wenking model LB 81 M, from Intelligent Controls GmbH, Clausthal-Zellerfeld

voltage scanner, Wenking MVS 87, from Intelligent Controls GmbH

DC measuring amplifier, type 72 WC, from Knick.

The relevant MTR-FE cladding materials used were high-purity aluminum (Al 99.5; material no.3.0255 from Honsel AG) as well as the alloys AlMg1 (material no. 3.3315.10 from Honsel AG) and AlMg2 (material no. 3.3325.10 from Honsel AG). After pickling with nitric acid and subsequent neutralization, these materials had the same surface as the cladding material of the MTR fuel elements. Test strips of the dimensions 20 mm*40mm*2.4mm were used to determine the mass loss due to corrosion. All material samples were cleaned with acetone prior to testing and then exposed to the respective brines in laboratory flasks using different test parameters. At fixed intervals, the samples were withdrawn, freed from adhering corrosion products, dried, weighed and exposed again to the brine. Corrosion products were removed with 5% nitric acid in an ultrasonic bath.

High-purity aluminum (Al 99.5) was used for the electrochemical investigations. The metal test strip was screwed into a specifically manufactured electrochemical measuring cell. The reference electrode was a calomel electrode (Hg/Hg2Cl2/Cl) with saturated potassium chloride solution (4.2 mol/l) as the electrolyte solution. The potential of the calomel reference electrode relative to the standard hydrogen electrode was +242 mV at 25C. The electrolyte solution of the reference electrode was continuously added through a needle to compensate local concentration changes of the electrolyte at the interface. For measurements at 90C the calomel electrode was brought to a temperature of 25C to maintain functionability. In order to determine the potentials of local surface areas, the reference electrode was provided with a Haber-Luggin capillary which had to be brought close to the sample surface. This capillary reduces the ohmic drop in voltage in the electrolytes (3). For measuring the rest potential, the electrode potential was measured in comparison to

the reference electrode using a voltmeter of very high internal resistance (>1012 ohm) to ensure that no current flows in this part of the circuit.
The corrosion behavior of the materials was examined in the following repository-relevant salt solutions:
Table I
Table II
The reference solution for all experiments was bidistilled water.
RESULTS AND DISCUSSION
In order to determine the mass loss, the aluminum materials were exposed to the three different repository-relevant brines in a first test series at a temperature of 90C.
Fig. 1
Figure 1 shows the percentage mass decrease of the materials for solution 2 plotted against the time of exposure. It can be clearly seen that Al 99.5 significantly differs from AlMg1 and AlMg2. Whereas the alloys lose between 1.5 and 2.5% of their mass after 120 days, the mass loss of aluminum 99.5 exceeds 25%. The same trend can be seen for solution 1, although less pronounced. For solution 3 the percentage mass losses of the materials amount to less than 1% after 120 days and are thus about the same as for distilled water. The high mass loss in solution 2 may be attributed to the extremely high magnesium chloride fraction. The hydrolysis of magnesium chloride increasingly leads to a release of hydrogen protons lowering the pH value. The increased proton concentration now has an essential influence on the metal/hydrogen redox pair. In comparison to the normal hydrogen electrode, the potential for aluminum is at more negative values. This means that aluminum is oxidized and hydrogen protons are reduced. The increased proton concentration now shifts the equilibrium of the redox pair towards oxidation of the metal. This leads to an increased release of aluminum cations and enhanced metal corrosion. Moreover, the chloride ions can penetrate into the oxide scale of the metal causing structural changes of this protective layer which contribute towards accelerating corrosion.
The second test series served to examine the influence of temperature on the corrosion rate. The corrosion behavior of Al 99.5, AlMg1 and AlMg2 was studied in solution 1 at room temperature and at 90 degrees Celsius. It can be seen from Fig. 2 that the temperature increase has a greatly accelerating effect on the corrosion rate of Al 99.5. The corrosion rate for Al 99.5 increases by about 109-fold. A similar increase was found for AlMg1, whereas even a 390-fold increase was observed for AlMg2. An increase of the reaction temperature changes the proton concentration. Thus, for example, a pH value of 4.52 is found for solution 1, whereas a pH value of 3.61 was measured at 90 degrees. The increased corrosion rate may also be explained here by the increase in proton concentration. The equilibrium is shifted in favor of metal oxidation and thus towards metal ion reselease. Moreover, kinetically induced processes cannot be ruled out, which are accelerated by the temperature increase and, in their turn, increasingly contribute towards corrosion.
Fig. 2
Furthermore, the influence of metallic additives was studied using those metal alloys (Hasteloy C4; stainless steel 1,4541 and GGG 40) which serve as cask materials.
The time-dependent variation of percentage mass decrease can be seen from Fig. 3. On the whole, the corrosion resistance of the cladding materials

significantly decreases in the presence of metallic additives. The mass of Al 99.5 decreased by 98% within less than 30 days when GGG 40 was added both to solution 1 and solution 2 at 90 degrees Celsius. The corrosion behavior of the cladding materials was only insignificantly influenced by the addition of GGG 40 in distilled water and in solution 3. In the presence of stainless steel 1,4541 and Hasteloy C4, the percentage mass decrease of Al 99.5 was 72% and 84%, respectively, in solution 1 after 50 days. The increase of the corrosion rate is to be attributed here to local element formation. Thus, for example, the aggressive solutions 1 and 2 lead to the release of iron cations from the cask materials in the first phase, which then react with aluminum in the second phase. The iron cations on the aluminum surface are thus reduced, involving simultaneous oxidation of the aluminum metal and dissolution of aluminum cations. The formation of such local elements is the reason for very rapid material corrosion.

Fig. 3

Additional experiments were carried out to study the influence of oxygen concentration and irradiation on the corrosion rate.

Experiments in an argon atmosphere did not show any change in comparison to the reference sample in air. No unambiguous result was achieved with materials exposed to gamma irradiation (8.7*103 rad per hour) during the experiment.

For the electrochemical studies the potential/time behavior of the Al 99.5 cladding material was examined in various brines at different temperatures. The time-dependent variation is shown in Fig. 4 for solution 1.

Fig. 4

The potentials initially decreased towards more negative values at elevated temperatures. The rapid decrease may be explained by the fact that the thin surface scale of the metal was not stable enough at elevated temperatures leading to deterioration. The subsequent increase of the potential values means that the surface scale is built up again in the medium establishing a more stable equilibrium, which is reflected in constant potential values. It is interesting to note that these stable potential values are lower for solutions 1 and 2 than for solution 3, which implies the presence of a thinner protective oxide scale on the metal surface in these media. In the absence of sufficient protection by a stable oxide scale, corrosion can then proceed much more rapidly in solutions 1 and 2.

CONCLUSION

In summary, it may be derived from the mass loss experiments that an increase in reaction temperature and the addition of GGG 40 to the aggressive repository-relevant brines 1 and 2 causes a drastic increase of the corrosion rate especially for the material Al 99.5. AlMg1 and AlMg2 did not show any corrosion resistance either.

The electrochemical experiments made it possible to quantitatively describe the different behavior of the oxide scales under the respective experimental conditions by recording potential-time curves. The correlation between the corrosion reaction, i.e. metal dissolution, and the oxide scale as the decisive electrochemical parameter of influence was established. The more stable the oxide scale on the metal surface, the slower is the corrosion rate. This result is in conformity with the results from mass loss experiments, and it confirms that the cladding

materials tested do not have a sufficient barrier function to avoid radionuclide release.
In the further course of experiments, spent fuel element sections will be exposed to the brines. The aim is to determine the source term so that release calculations can be established for the respective radionuclides.
These studies were supported by the Federal Ministry of Education, Science, Research and Technology under reference number 02E86547.

ABSTRACT
Power Reactor and Nuclear Fuel Development Corporation (PNC) has been developing radionuclides removal technique to get higher volume reduction for the low level liquid waste from the Tokai Reprocessing Plant (TRP). Experiments were done using actual concentrated liquid waste from the TRP. Radionuclides removal process mainly consists of coprecipitation with ultrafiltration and ion exchange. Results of decontamination factors obtained from this experiment are as follows;
1) Decontamination factor >1E+6 for alpha nuclides.
2) Decontamination factor for ruthenium and total beta nuclide is about 1E+2

INTRODUCTION

Power Reactor and Nuclear Fuel Development Corporation has been developing radionuclides removal technique to get higher volume reduction for the low level liquid waste from the reprocessing plant since 1986.(1) Experiments were done using liquid waste from the TRP. The radioactivity of the liquid waste is about 1E+4Bq/ml. Dominant radionuclides are plutonium, uranium, ruthenium and cesium. This liquid waste contains much amount of salt as sodium nitrate and sodium carbonate. Radionuclides removal process mainly consists of coprecipitation with ultrafiltration and ion exchange. This report focuses on the result of the examination about the characteristics of coprecipitation.

WASTE COMPOSITION AND SELECTION OF THE PROCESS

Waste Composition

Two types of low level liquid waste were used in the experiments; (2) the low level liquid waste (LAW), which is generated from the separation-refinement process, the analysis for quality control, etc., and the concentrated liquid waste (MAW). Typical MAW contains many kinds of alpha nuclides (plutonium, uranium, americium, etc.) and beta gamma nuclides (iodine, cerium, ruthenium, cesium, etc) in order of 1E+4Bq/ml. These test solutions also contain many kinds of salt at high concentration and a lot of impurities such as calcium, magnesium.

Selection of the Process

It is important that the process is composed of few unit to minimize the plant and reduce the secondary waste. However, the liquid waste contains many kinds of alpha nuclides (plutonium, uranium, americium, etc.) and beta gamma nuclides (iodine, cerium, ruthenium, cesium,strontium, etc.) so that it is necessary to combine some unit processes according to the chemical characteristics of each radionuclide. After many radionuclides removal techniques were investigated, the following techniques were selected.3) This process are shown in Fig. 1.

1) Iodine is precipitated as AgI by adding AgNO3 and filtrated by ultrafilter.

2) Alpha nuclides and most of the beta gamma nuclides are coprecipitated with Fe(OH)3 and filtrated by ultrafilter.

3) Strontium and cesium are adsorbed by sodium titanate resin and potassium cobalt ferrocyanide resin, respectively.

Fig. 1

OUTLINE OF THE PROCESS

Iodine Removal

After adding sodium sulfite to prevent volatilization of iodine, the pH is adjusted to 7 by nitric acid. At pH7, sodium sulfite is added again to convert iodate into iodide ion. After then, silver nitrate is added to precipitate iodine as silver iodade, which is filtrated by ultrafilter.

Decarbonation

Liquid temperature is kept at 80C with aeration after adding nitric acid to adjust pH to 1, so that carbonate ion and nitrite ion are removed to off-gas as CO2 and NOX gas. This process prevents plutonium and uranium from formation of carbonate complex at the next coprecipitation process.

Coprecipitation I

Ferric nitrate is added to the liquid waste and pH is adjusted to 10. The flocks of Fe(OH)3 generated are filtrated by ultrafilter. Alpha nuclides and most of the beta gamma nuclides are removed with iron flocks.(4,5)

Coprecipitation II

Ferric nitrate is added to the liquid waste and pH is adjusted to 7. The flocks of Fe(OH)3 generated are filtrated by ultrafilter. Amophoteric nuclides, such as antimony, are removed with iron flocks.

Ion Exchange

After the coprecipitation, strontium is adsorbed by sodium titanate resin and cesium is adsorbed by potassium cobalt ferrocyanide resin. Because calcium and magnesium are also adsorbed, sodium titanate resin is needed not only for strontium but also for calcium and magnesium.

EXPERIMENTAL RESULTS

Optimization of the Amount of Coprecipitant

The experiments were carried out to optimize the amount of the coprecipitant. The results are shown in Fig. 2. The more the coprecipitant is added, the bigger the decontamination factor for alpha nuclides becomes. The coprecipitation effect for two times is more

effective than for one time, but the second coprecipitation effect is much smaller than the first one. For the case of ruthenium, the increase of the coprecipitant makes decontamination factor slightly large, but the effect of repeating the coprecipitation are hardly observed. To obtain a large volume reduction ratio, the amount of coprecipitant should be as small as possible to get enough decontamination factor. Moreover, the concentration limit by ultrafilter is 15,000mg/l for iron. To get enough decontamination factor and 1/100 volume reduction by ultrafilter, the amount of coprecipitant is determined as 150mg/l for iron. The frequency of coprecipitation process is determined as one time for the following reasons; 1) small effect of the second coprecipitation, 2) not disturb the volume reduction ratio, and 3) avoid the increase of equipment. Axis of abscissas shows the amount of the coprecipitatant converted into the iron concentration. Axis of ordinates shows decontamination factor get by the coprecipitation and the ultrafiltration. The white points show the data of the coprecipitation for two times, while the black points show the data for one time.

Fig. 2

Effect on Alpha Nuclide Removal

Decarbonation process

Carbonate ion in the liquid waste is considered to form stable carbonate complexes with plutonium and uranium, which are hard to coprecipitate with Fe(OH)3, so it must be removed before the coprecipitation. The experiments using MAW were carried out to confirm the effect of the removal of carbonate ion on the coprecipitation of alpha nuclides. The results are shown in Table I. Decontamination factor of the coprecipitation after the decarbonation is more than the order of 1E+2, while decontamination factor is nearly equal to 1 without decarbonation. The decarbonation process is necessary for effective coprecipitation of alpha nuclides.

Table I

Phosphate ion

The experiments using the liquid waste which had highly phosphate content (max.8g/l) were carried out. The results are shown in Table II. Compared with the results of the experiments using MAW, which has low phosphate concentration (<90mg/l), phosphate ion affects on the removal of alpha nuclides by coprecipitation.

Table II

Effect on Ruthenium Removal (6,7,8,9)

Addition of non-radioactive ruthenium

The experiments were carried out to confirm the effects of addition of non-radioactive ruthenium. Before the experiment of coprecipitation for the radioactive nuclide, 135mg/l of non-radioactive ruthenium is added as Ru(NO3)3. The results are shown in Table III. As it shows, the addition of non-radioactive ruthenium is not so effective to remove ruthenium in the liquid waste.

Table III

Coprecipitation with CoS

Ruthenium removal by coprecipitation with CoS was attempted by using LAW, which already treated in the process shown in Fig. 1.(10) After addition of cobalt nitrate, pH is adjusted to 9.5 and 4% thioacetamide is added at 60C with stirring to generate CoS flock. After cooling, CoS flock is filtrated by the ultrafilter. The results are shown in Table IV.

Ruthenium is still detected after the coprecipitation, so that this treatment is not so effective, too.

Table IV

Adsorption by the zinc electrode posited charcoal

Ruthenium removal by adsorption by the zinc electrode posited charcoal (Zn-C) was attempted using treated LAW same as the method described in the section 4.3.2. The liquid waste passed through the Zn-C column. The results are shown in Table V. The concentration of Ru becomes below the detection limit and more than 1E+3 of decontamination factor values of the whole process are obtained in all the experiments. The zinc electrode posited charcoal is effective for removal of ruthenium, but it is necessary to confirm the continuation of effective removal condition. According to the literature,11) 12) such good condition does not last so long. It is also necessary to obtain the optimized the operation condition to minimize the yield of secondary wastes.

Table V

TOTAL RADIONUCLIDE REMOVAL EFFICIENCY

Finally, the MAW was treated through the nuclide removal process in the following conditions; the 150mg/l of coprecipitant as iron, without the mixture of highly phosphate ion content liquid waste, and the amount of the coprecipitant are the same as the condition described in the section 4.1.-4.3. The results are shown in Table VI. Good decontamination factor were obtained about almost all the radionuclides, especially about alpha radionuclides, however decontamination factor of ruthenium was about 1E+2.

Table VI

CONCLUSION

By using coprecipitants with ultrafilter and ion exchange resin, decontamination factor over 1E+6 for total alpha nuclides were obtained for the low level liquid waste from the TRP. And from now, research and development for higher volume reduction, less secondary waste and improvement of the beta gamma radionuclides removal efficiency especially for ruthenium will be executed.

K BASINS SPENT NUCLEAR FUEL REMOVAL AND CONDITIONING

Richard A. Bastar
Parsons Infrastructure & Technology Group, Inc.
(509) 943-0909

ABSTRACT

In February 1995, the U.S. Department of Energy (DOE) committed to relocate more than 100,000 individual spent nuclear fuel (SNF) assemblies from wet storage facilities on the Hanford Site in Eastern Washington State, to a dry storage facility. The scheduled start date for fuel retrieval operations is December 1997, and completion is scheduled for December 1999. Parsons Infrastructure & Technology Group, Inc. (Parsons) was tasked by Westinghouse Hanford Company (WHC) to develop a trade study that compared alternatives for SNF retrieval from wet storage and SNF conditioning prior to dry storage. The results of the trade study were used by WHC to support selection of the alternative that would accomplish SNF relocation operations in the safest and most cost-efficient manner. Each alternative focused on two major functions: The SNF Retrieval Operations and SNF Conditioning. The SNF Retrieval Operations consisted of evaluating four distinct alternatives for fuel handling, fuel cleaning, and fuel packaging. The three SNF Conditioning alternatives included vacuum drying the fuel at ambient temperature, vacuum drying the fuel using the decay heat of the fuel, and vacuum drying the fuel by applying supplemental heat to the fuel at a temperature of 350oC. Conceptual designs of the equipment required to perform various functions were developed. The quantity and types of equipment selected was expected to support a schedule for placement of the SNF in dry storage within a two-year period. Time-motion studies were performed to evaluate schedule impacts and expected radiation dose to workers. A life-cycle cost estimate was developed, and included construction and operating costs for each of the alternatives evaluated.

After all data was fully developed, a summary evaluation was performed to compare the fuel retrieval and conditioning alternatives in terms of cost, dose, schedule, and complexity. The evaluation showed that tradeoffs were such that three of the four retrieval concepts, coupled with SNF drying using the supplemental heating alternative, were nearly equivalent. These three retrieval alternatives are leaving the fuel intact in their present storage canisters, modifying their present

storage canisters to allow limited fuel flushing, and removing the fuel from their canisters for cleaning. The trade study results and recommendations were used by WHC to support the selection of the recommended "Path Forward," which is the strategy for placement of the SNF in dry storage.

The Path Forward recommendations made by WHC, subsequent to issuing the trade study, were to remove the SNF from their canisters, thoroughly clean the SNF, remove the water from the fuel using a vacuum drying process, and then remove the residual and bound water using the supplemental heat vacuum drying process.

INTRODUCTION

In February 1995, the DOE approved the Spent Nuclear Fuel Project Path Forward recommendation for resolution of the safety and environmental concerns associated with the deteriorating SNF stored in the Hanford Site's K Basins. The K Basins consist of fuel pools within two Production Reactor buildings near the Columbia River. The Path Forward recommendation described the facilities and processes required to safely retrieve, package, transport, condition, and dry store the K Basin Fuel. In addition to approval of the Path Forward, the DOE committed to an accelerated schedule to begin fuel removal from the K Basins by December 1997, and complete it by December 1999.

In response to DOE's goals, WHC initiated a project to further develop the technical baseline for the Spent Nuclear Fuel Removal and Conditioning Project. Parsons was tasked to develop concepts for removing the spent nuclear fuel from the K Basins, conditioning the fuel for dry storage, and evaluating and documenting the results in a Trade Study Report. The study goal was to delineate the systems and processes required to perform those functions, and to evaluate the life-cycle costs, personnel exposure levels, schedule for fuel removal, risks and uncertainties, and impacts of these interfacing systems.

Approximately 2,100 metric tons of uranium in the form of more than 100,000 individual SNF assemblies are presently stored in canisters in the K Basins. Most of the SNF originated in the N Reactor facility and is low-enriched, metallic uranium, clad in Zircaloy. A typical SNF assembly is approximately 26 in. Long and 2.4 in. In dia. A SNF assembly is made up of on inner SNF element with cladding, and an outer SNF element with cladding. The inner SNF element has a small-diameter hole in the center and is held in place with springs; however, many of the springs have corroded and may not be in place. There are four types of canisters in the K Basins. Each canister has two barrels made of either stainless steel or aluminum, and holds up to 14 fuel assemblies; however, not all of the canisters are full and some of the SNF elements are broken. A significant fraction of this fuel has become degraded caused by cladding breaches during reactor discharge and subsequent corrosion during underwater storage.

Both of the K Basins are constructed of reinforced concrete and were placed in service in the early 1950s. They are located within 0.25 mile of the Columbia River. K West Basin was cleaned, refurbished, and epoxy-coated in 1981. The SNF in K West Basin is stored in closed, stainless-steel or aluminum canisters. Visually, these canisters appear to be in good condition.

K East Basin was not refurbished or epoxy-coated; it has been used to store N Reactor fuel since 1975. Fuel is stored there in open, stainless-steel or aluminum canisters. Degradation of the aluminum canisters and

breached fuel appears to be substantial. The water in the K East Basin is radioactively contaminated, and area dose rates near the pool surface are relatively high. Significant quantities of sludge to a depth of nearly 1 ft. are visible in some pool locations.

ALTERNATIVE CONCEPTS DEVELOPED

The Trade Study addressed many aspects of the fuel retrieval and conditioning operations outlined in the original Spent Nuclear Fuel Project Path Forward. The concept scope included developing equipment that would safely retrieve and handle the fuel bearing canister from racks at the bottom of the fuel pools. Equipment was conceptualized that would clean the sludge and corrosion products from the SNF elements. Variations in the equipment configurations allowed cleaning the fuel while it remained in the canisters, or after removal from the canisters. Systems were designed to minimize the amount of sludge released into the fuel pools during the fuel retrieval and cleaning operations. Fuel handling equipment and methods were developed for loading the fuel into the primary containment vessel called the Multi-Canister Overpack (MCO). The MCO is a 24-in.-dia., 160-in.-tall, stainless-steel vessel. After the fuel is loaded into the MCO, the MCO is welded closed and the water is removed. Residual water left in the MCO will be removed by one or more vacuum conditioning processes. The basic functions addressed in the trade study are shown in Fig. 1.

SNF Retrieval Concepts

The alternative methods for SNF and canister retrieval, cleaning, and MCO loading required developing methods for performing, handling, and machining operations in an underwater environment. The four separate concepts evaluated were as follows:

Concept 1A, As-Is, Direct loading of the SNF canisters into the MCOs;

Concept 1, Limited Cleaning, Limited flushing of the SNF in the canisters prior to MCO loading;

Concept 2, Slotting and Flushing, Canister machining and rigorous SNF flushing in the canister prior to MCO loading; and

Concept 3, Separate Fuel from Canister, Removal of the SNF from the canisters, and rigorous SNF and canister cleaning prior to MCO loading and fuel reracking in baskets.

Fig. 1

Spent Nuclear Fuel Conditioning Concepts

S-1, Dewatering and Drying, The S-1 conditioning effort was in the initial conditioning step required for all scenarios. Step S-1 is accomplished by draining/pumping the free water from the MCO, followed by low-temperature "cold" vacuum drying.

S-2, Cold Vacuum Conditioning, This step was one of the two "complete drying" steps to further dry the contents of the MCO. Step S-2 is accomplished by using only the fuel decay heat over time to heat and dry the fuel.

S-3, Hot Vacuum Conditioning, This step was the second "complete drying" steps to further dry the contents of the MCO. Step S-3 drying would be accomplished by using supplemental heating of the MCO (to approximately 300oC), and holding the fuel at this temperature and under vacuum to remove nearly all retained moisture from the fuel and corrosion products within the MCO.

Figure 2 shows the three alternatives for dewatering and vacuum drying the fuel in the MCO, and includes the calculated number of stations required to condition all fuel within a two-year period.

Trade Study Development

Equipment concepts were developed that could perform the various functions of the process, from fuel retrieval through final storage. Equipment layouts were made showing equipment in the K Basin Facilities and in new facilities. Figure 3 shows a typical process equipment layout in a K Basin pool. With the time restriction of two years for complete fuel retrieval, some of the systems required redundant equipment items. All fuel retrieval alternatives will be performed in the two K Basin Facilities. The current process logic for fuel conditioning allows conditioning steps to be performed at one or more of four distinctly different facilities in different locations. These four facilities are the K Basin(s), the K Basin Annex(es), the Canister Storage Building (CSB), and the conditioning facility. The CSB Annex was added as a fifth facility, and although considered a separate alternative, it would actually be a part of the CSB. Depending on a number of different factors (including facility space available to perform conditioning operations, shipment conditions of the MCOs, location of the facilities themselves in relation to Hanford Site boundaries, MCO transportation constraints, etc.), a given conditioning step may not be amenable to perform at a given facility, or may be done much more efficiently and logically at one facility, versus another.

Figure 4 shows option paths evaluated. These were based on 24 (18 paths plus 6, S-1 at the CSB Annex) feasible processing paths. Each path has one of two choices for MCO loadout. These consist of either remote loading or water-shield loading, which brings the total number of options to 48.

After the equipment concepts and layouts were produced, time-motion studies were performed for all operations, from fuel retrieval in the K basins through final placement of the MCOs containing the fuel into the CSB. Activities were defined and the crew sizes required to carry out each activity were established. These studies revealed that the Crane Availability in each of the K Basins was the limiting factor for meeting the two year fuel removal schedule. The results of the time-motion studies were then used as input to define the approximate total person-dose received by workers during the fuel removal operations. Doses were calculated using the computer dose modeling code Microshield.

A cost estimate for each of the alternatives was developed. As the basis for the cost estimates included in the trade study, it was assumed that construction and modifications to facilities would be performed by the onsite construction contractor, ICF Kaiser Hanford, and the operation of facilities and equipment would be performed by WHC personnel. Sketches, drawings and descriptions were used to establish quantities of equipment required, building areas, configurations, and construction types, as well as installation complexity. Because the level of detail of the design documents lacked the final design detail, a contingency factor was applied to the estimates.

Fig. 2

Fig. 3

Fig. 4

EVALUATION CRITERIA

The fuel removal and conditioning concepts developed were evaluated and compared to ascertain their potentials for meeting cost, schedule, technical, and other requirements. The evaluation used a systems engineering approach for assessing the fuel removal and conditioning

alternatives. It facilitated a side-by-side comparison of functions and requirements of the fuel handling and processing alternatives. Key criteria were established and used to perform the evaluation. They consisted of: 1) Cost--Total of both acquisition and operating costs in dollars; 2) Exposure risk--(dose) in person-rem; 3) Complexity - this criterion included the potential for leaving residual moisture in the MCO after drying; and operability and maintainability considerations, including operations steps, special handling, and operations simplicity. The rankings were based on the professional judgement of the evaluators and ranged from 1 (least potential) to 4 (most potential). Each alternative was included in an option description worksheet. The data was then plotted and compared by concept to show the options that minimized cost, dose complexity, and schedule. (Table I).

Table I

TRADE STUDY EVALUATION RESULTS

Comparisons between the various alternatives (Table I) were made in terms of cost, schedule, dose to workers, and operational complexity. The results of the evaluation showed that Concept 2 with S-1, S-2, or S-3 conditioning was not a favorable option because of a higher cost, schedule, and dose to workers than any other options. The evaluation results also show that the tradeoffs of cost, schedule, dose, and complexity in Concepts 1, 1A, and 3 with S-1/S-3 conditioning are such that these concepts are nearly equivalent.

Concept 1A, As-Is

Concept 1A operations consist of essentially three steps: 1) Retrieving the canisters; 2) Removing the canister lids; and 3) Loading the MCOs. S-1/S-3 conditioning at the new conditioning facility offers the most efficient method of conditioning, with the least amount of time and equipment required per MCO. Based on the evaluation data, this concept scored favorably in both cost and dose received by workers when conditioning Step S-3 was used. Concept 1A required the minimum amount of equipment and the minimum number of operations to perform fuel removal operations in the K Basin. The capital and operating costs of the alternative with S-3 conditioning are relatively low because of the absence of complex equipment for fuel retrieval. Fuel handling activities by remote or underwater methods limit direct exposure to personnel. The minimization of fuel handling activities in the K Basin process area translates into less worker dose.

The estimated time it takes to perform fuel removal operations was moderate in relation to the other concepts. The primary driver behind the fuel removal schedule is the availability of the crane to perform various functions during MCO loadout, shield plug welding, and cask transfer operations. A disadvantage to Concept 1A is the unknown state of the fuel and sludge after the MCO is sealed. Concept 1A fuel removal with S-2 conditioning shows a substantial increase in acquisition costs because of the increased operations and equipment costs of the conditioning process.

Concept 1, Limited Cleaning

Concept 1 operations consisted of essentially four steps: 1) Retrieving the canisters; 2) Removing the canister lids; 3) Flushing the canister/fuel; and 4) Loading the MCO. Compared to Concept 1A with either S-2 or S-3 conditioning, the major difference in the data shown on the evaluation table is that this concept has generally higher total costs and dose to workers. The higher costs and higher personnel doses are attributed to additional equipment costs and additional operating times

respectively, to perform the flushing activities. Schedule and complexity score relatively the same as Concept 1A.

Concept 2, Slotting and Flushing

Concept 2 operations consist of five steps: 1) Retrieving the canisters; 2) Removing the canister lids; 3) Machining the canister; 4) Flushing the canister/fuel; and 5) Loading the MCO. This concept is shown to be generally not a favorable option. Total costs are relatively high because of the increased complexity of canister and fuel handling equipment required for machining the canisters, and the increased time it takes to perform all fuel removal operations. Dose rates are unfavorable and reflect the doses operators would received while performing basin operations for greater than 100 weeks. This concept with either S-2 or S-3 conditioning has generally the worst scores in all categories the criteria evaluated. An advantage to this concept is that a quantity of sludge and corrosion presently in the canisters and on the fuel will be removed, and will provide improved conditioning products.

Concept 3, Separate Fuel from Canister

Concept 3 with either S-1/S-2 or S-1/S-3 conditioning at various locations was evaluated. Concept 3 operations consist of six steps: 1) Retrieving the canisters; 2) Removing the canister lids; 3) Removing the fuel from the canisters; 4) Cleaning the fuel; 5) Reracking the fuel in baskets; and 6) Loading the MCO (this doubles the fuel packing density of Concept 1A, 1 and 2). Dose rates encountered in this process are approximately 30% higher than the doses calculated for Concepts 1A and 1. The reason for the increased doses for the concept is because of the increased number of manhours actually spent in the basin area for fuel repacking. The schedule for fuel removal is improved (approximately 55 weeks or approximately one-half of Concept 1A and 1) because of concurrent processing of "good" and "bad" fuel, and the 50% reduction in the number of MCOs needed for complete fuel removal from the Basins. Costs for the option using Concept 3 are generally less than the other options because of lower acquisition costs for MCOs, and lower labor costs for MCO and cask handling activities. The schedule advantage of this concept seems to present an attractive alternative. Improved knowledge of sludge and corrosion product inventories in the MCOs after fuel rod cleaning will prove advantageous during the fuel conditioning operations. This knowledge will also improve confidence in the determination of the fuel condition future years, when the fuel is processed for final disposal.

CONCLUSION

Subsequent to the trade study completion, WHC refined the Path Forward to reflect Parsons recommended approach for fuel retrieval and conditioning. That approach shows repacking the bare fuel in storage baskets (Concept 3) and applying a two-step fuel drying and conditioning process (S-1/S-3).

7-6

AT-LINE DETERMINATION OF VOCs IN WASTE DRUM HEADSPACE WITH FOURIER TRANSFORM INFRARED SPECTROSCOPY

Qubec, Qubec Canada G2E 5S5
ABSTRACT
Transuranic (TRU) radioactive wastes have been retrievably stored in waste drums at Department of Energy (DOE) sites since the 1970's. Ultimately, these waste drums are destined for final disposition in the Waste Isolation Pilot Plant (WIPP). Current requirements for acceptance of waste into the WIPP dictate that a representative drum headspace sample be acquired and analyzed prior to the transport and disposal of waste in the WIPP. Analysis results of the headspace sample are to be used for waste characterization, verification of process knowledge, assigning Environmental Protection Agency (EPA) hazardous waste codes, determining the potential for flammability, and as input to gas generation and transport models. Because of the very large number of waste drums and the rate at which they will need to be processed, a rapid, simple and reliable analysis method for waste drum headspace that can be performed "at-line" is necessary. Fourier transform infrared (FTIR) spectroscopy was selected because the analysis times are short, operation of the instrumentation is simple and reliable and because FTIR systems are rugged and can be easily configured to function for "at-line" analysis. Drum headspace samples are pulled directly into a cell mounted on an FTIR spectrometer and a spectrum recorded. From each infrared spectrum, 29 volatile organic compounds, the C1-C3 hydrocarbons, and some interferences are identified and quantitated. To evaluate the analytical performance of the FTIR system and methodology on real samples, over 200 gaseous samples of actual TRU waste drum headspace and the headspace of other inner layers of confinement within the waste drums have been analyzed by an "at-line" FTIR system. Analytical results are available within 5-6 minutes of sample collection. The FTIR analysis results were compared to the results from duplicate samples that were collected in SUMMA canisters and analyzed by the standard laboratory gas chromatographic (GC) methods. The FTIR analysis results agree well with the chromatographic analyses and will meet the program required limits for accuracy and precision for the analytes of interest. To date, the results indicate that FTIR spectroscopy is a viable, cost effective alternative to the laboratory based GC methods currently specified for the analysis of TRU waste drum headspace.
INTRODUCTION
Transuranic (TRU) wastes have been retrievably stored at Department of Energy (DOE) facilities since the 1970s. In 1980, the Waste Isolation Pilot Plant (WIPP) was authorized and funded to provide a research and development facility focused upon demonstrating the safe disposal of radioactive wastes. Because of the wide variety of activities that generated DOE's TRU waste, some of the waste also contains components that are regulated by the Resource Conservation and Recovery Act (RCRA). To ensure that the waste to be admitted to the WIPP meets a variety of compliance programs, including RCRA, the TRU Waste Characterization Program (TWCP) was initiated. Waste characterization data from the TWCP will be, and currently are being used, to support the assessment of WIPP repository performance, the application for permits and variances issued

by regulatory agencies, and necessary revisions to transportation restrictions.

The EPA in its conditional no-migration determination for the WIPP,(1) indicated that before DOE submits a petition for the actual disposal phase at the WIPP, real sampling and analytical data would be required to characterize the waste. Among the chemical analyses requested is the determination of volatile organic compounds (VOCs) in the headspace of the waste drums and all additional layers of confinement within each waste drum. The VOC data are necessary to evaluate the potential for migration of these compounds beyond the WIPP boundary above EPA determined health based risk limits (2) and to confirm that the waste drum headspace is representative of the drum contents. The EPA is also requiring quantitative data for the flammable VOCs, hydrogen and methane prior to disposal at the WIPP. Due to the potential for explosive mixtures in waste drum headspace, EPA has currently imposed a 500 ppmv concentration limit for total flammable VOCs in the headspace of containers to be sent to the WIPP during the test phase.

A list of 29 VOCs was compiled from examination of available records associated with the descriptions of the activities that may have generated waste within the DOE complex and from actual records describing the stored wastes. Exposure and lower explosion limits of these compounds are indicators of what concentrations might be of reasonable concern for waste handling and storage. Some characterization of stored TRU waste which included some headspace analysis has been performed and reported.(3) Generally, fewer then 5 of the identified VOCs are found in any particular sample.

At the Idaho National Engineering Laboratory (INEL) alone, there are as many as 140,000 containers of TRU waste. Most of these containers are 55-gallon drums with sealed lids. Due to the potential buildup of flammable gases in these drums from radiolysis, these drums are to be vented and appropriate filters installed in the lid to allow the drum to aspirate. At the time of filter insertion, it is desirable to collect and analyze a sample of the headspace for characterization and classification purposes. Because of the number of drums that need to be vented, the INEL has designed and built an automated Drum Venting Facility (DVF) that will vent drums at the rate of one every 5-10 minutes. As part of this facility it is desirable to have a rapid VOC analysis technique to provide near-real time feedback of analysis results to dictate the immediate storage and handling requirements for each drum. In the Waste Characterization Area (WCA) located at Argonne National Laboratory-West (ANL-W), waste drums are opened for detailed characterization and examination. A rapid VOC analysis technique is also desirable at the WCA since all layers of confinement within each drum need to be sampled for VOCs, CH4 and H2 analysis.

The currently accepted methods for the analysis of waste drum headspace components are gas chromatography with thermal conductivity detection (GC/TCD), gas chromatography with flame ionization detection (GC/FID) and gas chromatography with mass spectrometric detection (GC/MS).(4) A typical sampling and analysis of waste drum headspace consists of collecting the gaseous sample in a SUMMA canister, surveying for radioactive contamination, transporting it to the laboratory, an initial dilution, screening via GC/FID analysis, the final dilution, GC/MS analysis for VOCs, GC/TCD analysis for H2 and CH4, and finally reporting in data packages. The total cost for each analysis is ~$1000 and the

turnaround time is as much 1 month, primarily because of the data reduction and reporting requirements. Minimum actual analysis times would be 15-45 minutes per chromatogram once the sample is received in the laboratory.

Because of the time necessary to develop a typical chromatogram, chromatography is not a preferred technique for the at-line analyses outlined above. This is particularly true if dilution is required to get the sample into the working analytical range. Some "high-speed" chromatography applications exist; however, they suffer from reproducibility problems without special sample inlet systems, must sacrifice chromatographic resolution for analysis time, and often more than one column/chromatographic system must be used to quantitate multiple analytes.(5,6) Separate columns are also necessary for the analysis of permanent gases such as H_2, CH_4, and CO_2.

A reasonable alternative to at-line GC instrumentation for the analysis of waste drum headspace is Fourier transform infrared spectroscopy (FTIRS). Rugged FTIRS instrumentation is commercially available and has been used for several on-line applications.(7,8) Depending upon the instrument/detector used, analysis times using FTIRS can be as short as 1 second, however, analysis times of 1-5 minutes are more common. Most VOCs and permanent gases can be analyzed with infrared spectroscopy. Exceptions include diatomic molecules without dipoles such as H_2 and O_2. Because of the nature of absorption spectroscopy, calibrations/standardizations can be universal within certain limitations, i.e once a calibration/standardization is established it is possible to transfer this calibration from instrument to instrument, provided that the data are collected under similar conditions.(9)

The goal of the work outlined in this paper was to evaluate and determine if FTIRS is a suitable alternative to GC methods for the "at-line" analysis of waste drum headspace in order to support various decisions about whether the waste drums meet TWCP requirements and certain WIPP Waste Acceptance Criteria. The basic questions lie in whether analysis by FTIRS produces statistically equivalent results as the GC procedures and/or whether it meets other TWCP criteria for precision (25%) and accuracy (30%).(4)

EXPERIMENTAL

Bomem furnished the FTIR based VOC system as specified by the INEL. Because the "turn-key" FTIR system is located in a "suspect radiation contamination zone" near where the waste drums are handled and mounted into the waste characterization hot cell at the WCA, the hardware is housed in a NEMA 12 enclosure (48 in. tall x 36 in. wide x 16 in. deep) for protection from damage and from contamination by radiation. Figure 1 is a schematic of the components comprising the FTIR based VOC analysis system. In the NEMA 12 enclosure, a Bomem MB 100 series FTIR is vertically mounted and equipped with a specially designed top plate. The optical bench is purged with hydrocarbon and CO_2 free dry air which is vented into the NEMA 12 enclosure to help maintain a slight positive pressure within the enclosure. A 20 cm gas cell with zinc selenide windows with an antireflection coating to reduce the refractive index and a DTGS detector are mounted on the top plate. All sample transfer lines and the sample cell are maintained at 110C. Transducers are mounted in the cell to record the temperature and pressure of each sample. Because of the heat load supplied by the instrumentation and the other heated components, the NEMA 12 enclosure is cooled and maintained at ~28C with a

closed cycle air conditioner. Operation of the valves and the FTIR are controlled via RS422 from a 486 based PC located >60 feet away at the WCA control center.
Fig. 1
Sampling and analysis is initiated when the start signal is received from the GSS computer. At this point, the three way valve (V1) rotates toward the sample line, and the cell and lines are evacuated to <2.5 Torr by opening V4. The cell and lines are backfilled to ~625 Torr with hydrocarbon and CO2 free dry air by closing V4 and opening V3. The cell and lines are reevacuated by closing V3 and opening V4. Once evacuated to <2. 5 Torr, V4 is closed and the "ready evacuated" signal is sent to the GSS computer, which then opens V0, and the lines and cell begin to fill with the sample. When the pressure has stabilized, spectral acquisition is initiated. Each spectrum is the result of 10 coadded scans. A second spectrum of a "diluted" sample can be acquired by rotating V1 toward the air line and then opening V2 until the desired lower pressure is obtained, then the cell is backfilled to 640 Torr with hydrocarbon and CO2 free dry air.
Because quantitative IR spectra of several of the VOC's of interest were not available at all or not available at the conditions at which the sample spectra were to be recorded, it was decided to record the quantitative spectra at the sampling conditions, i.e., at 110C with a nominal pressure of 640 Torr (near ambient pressure in eastern Idaho). Bomem assembled a second system at their facilities with a gas sampling manifold that included a cold finger to trap VOCs and a MB 100 series Fourier transform infrared spectrophotometer with an identical top plate to that provided the INEL. To collect a pure component spectrum of a particular VOC, a sample of the neat analyte was put into the cold finger and then the finger was attached to the manifold and the sample was frozen with liquid nitrogen. The space over the frozen sample in the cold finger, manifold, and heated gas cell were evacuated using a mechanical and a turbo pump in series. Once a stable vacuum was reached, the cold finger containing the sample was isolated by closing the valve, the liquid nitrogen was removed, and the sample heated to room temperature. The valve to the sample was then opened and the sample allowed to "evaporate" into the evacuated manifold and cell until the desired partial pressure of the analyte was reached (usually ~0.64 Torr). The total pressure was then brought to 640 Torr with nitrogen (i.e. 1000 ppmv) and the spectrum was acquired with 50 coadded scans at 1 cm-1 resolution. Many of the more polar and less volatile VOC's presented problems that were likely due to adsorption of the analyte onto the walls of the cell and manifold. The addition of nitrogen to the sample to bring it to 640 Torr seemed to enhance the instability of the analyte partial pressure. For these cases, additional nitrogen was not added to bring the total pressure to 640 Torr. There were no apparent differences in the spectral features of the analyte spectra recorded at low and high pressure. Linearity of the samples created in this manifold system was verified by using carbon tetrachloride to construct a calibration curve from 0 to 1000 ppmv. Carbon tetrachloride was selected because of its very high absorbtivity coefficient.
Examination of IR spectra of actual waste drum headspace indicated that interferences that were not included in the original calibration set were often encountered. These interferences included NH3, N2O, trimethylamine, >C6 hydrocarbons and very wide concentration ranges of CO2. To compensate

as much as possible for very wide ranging CO2 concentrations, a series of six CO2 standards were prepared that when combined with the existing 2500 and 25000 ppmv CO2 spectra covered the range from 2500-50,000 ppmv. Certified 1000 ppmv standards of N2O and NH3 were purchased from Scott Specialty Gases (Plumsteadville, PA). A certified 1000 ppmv standard of trimethylamine was purchased from SO-CAL Airgas (Los Angeles, CA). A hydrocarbon standard was prepared at 955 ppmv from decane (333 ppmv), undecane (322 ppmv) and dodecane (300 ppmv). Spectra of each of these standards were collected on the "turn-key" system installed at the WCA or an identical system intended for installation at the DVF.

Quantitative analysis of the VOC's from the infrared spectra collected on the "turn-key" FTIRS system was performed using PLS.(10) The PLS analysis methods on the "turn-key" FTIRS system were generated using Galactic Industries PLSplus add-on package to Grams/386. Because of software limitations and the cumbersome calibration sets required for a single method that would quantitate all 29 target VOC's and the C1-C3 hydrocarbons, individual PLS methods were used for each analyte in an optimally selected region of the spectrum for that analyte. Calibration sets consisted of the original calibration set supplied by Bomem and the supplemental interference spectra collected at the WCA (n=110). All spectra in the set were background corrected to avoid extraneous factors that might affect quantitation of an analyte. Artificial spectra containing offsets and sloping lines were added to the set for simple background factor definition. Frequency regions for each analyte were selected after evaluating the correlation spectra for that component calculated by a development aid in the PLSplus package and the actual spectrum of the analyte. An optimum number of factors for each analyte method were selected from the evaluation of the predicted residual error sum of squares (PRESS) values determined using the cross-validation procedure included in the PLSplus package. A summary of the frequency regions and factors used in these methods is given in Table I. Evaluation of an unknown spectrum for the 29 VOC analytes and methane, ethane, and propane using 32 separate PLS methods takes ~10 seconds. A complete analysis and report are provided to the operator within 3-6 minutes of sample introduction to the system.

Table I

RESULTS AND DISCUSSION

The suitability of using FTIRS for the at-line determination of VOCs in waste drum headspace was evaluated by several means. Routine daily FTIR analysis of a check standard was used to assess long term precision, accuracy and determine subsequent working detection limits. Direct comparisons were made between the FTIRS results and results from "identical" samples collected in SUMMATM canisters. Further assessments of accuracy, precision and error rates were accomplished by participation in the TWCP Performance Demonstration Program.(11)

During operations at the WCA, prior to any sample collection or analysis on a given day, a check standard was analyzed by the FTIRS and occasionally sampled into a SUMMATM canister for later analysis by GC methods. A summary of the results from the analysis of these check standards is presented in Table II. Two separate standards were used over a period of ~6 months, each for ~3 months. The current sampling manifold design at the WCA requires that the check standards be transported through ~25 feet of unheated tubing prior to reaching a heated portion of the manifold. Polar VOCs tend to interact with the walls of the tubing

and are not efficiently transported without heat or the presence of a more polar compound to displace it from the active sites on the surface. This problem is clearly reflected in the recovery and precision for the analysis of methanol by both the FTIRS and GC analyses of the first standard which was dry. Addition of water to a low pressure gas standard containing polar VOCs which was then sampled through the same tubing demonstrated that methanol could be quantitatively transferred through this tubing if a more polar compound was present to compete for binding sites. A second standard was ordered that contained water, however methanol was still no efficiently reaching the manifold. At 500 psig, some of the water apparently condensed in the cylinder and some of the methanol was lost in the condensation.

Table II

Examination of Table II indicates that aside from the problem with the methanol transport, the FTIRS method performed well and was within the TWCP requirements for 30% accuracy and 25% precision. Long term precision for the FTIRS method is most typically <10%. Accuracy for all analytes in Table II, except methanol, is within the TWCP requirement, however they appear to be 5-15% negatively biased. The GC analyses for some analytes also appear to be biased, but in a positive direction, e.g. 11-dichloroethane and 11-dichloroethene.

Because FTIRS spectra of headspace VOC samples are highly overlapped, direct analysis of the spectrum is difficult at best and special data processing like PLS is required to simplify the analysis. Each compound has a unique IR spectrum, which is the fact that allows the PLS algorithm to easily extract the necessary qualitative and quantitative information from a highly overlapped spectrum. The results can be slightly affected by the number and identity of the analytes present in the sample spectrum. Because of this, the determination of appropriate detection limits is not necessarily obvious. The components in the check standards were selected primarily because of how frequently they occur in the actual waste drum headspace samples. The were secondarily selected to represent classes of compounds. Rarely are more than 5 VOCs found in a given headspace sample. The analysis of the check standards for all VOCs of interest should therefore be representative of the samples and the long term precision should be representative of the actual sample analysis. Because of the representativeness of this standard and analysis, the precision times 3 is also an appropriate working detection limit for the FTIRS analysis. The detection limits shown in Table I were calculated from the repeated analysis of these check standards. These detection limits compare well with and are only slightly higher than published detection limits(12), as expected sine the published detection limits were obtained under optimum conditions.

During operations at the WCA, headspace samples from waste drums and all layers of confinement within the waste drums were sampled in to 250 mL SUMMA canisters for later analysis by standard GC methods. If the headspace volume was deemed sufficient, a second sample was collected directly into the at-line FTIRS system for immediate analysis. In all, 231 samples were collected and analyzed by both the GC methods and FTIRS. Of these 231 samples, 15 represent direct comparison of the FTIRS and GC/GC-MS for the two reference standards. In the actual headspace samples, 111-trichloroethane was found in nearly all samples. Trichloroethene, 11-dichloroethene, acetone, toluene, methanol and carbon tetrachloride were also found in some samples. Only 111-trichloroethane

and trichloroethene were found at significant concentrations in the samples.

Overall, for the samples that were above the detection limits for both GC/GC-MS and FTIRS the correlation line for 111-trichloroethane was FTIRS=(0.9960.014)*GC-(217) with an R2 of 0.958. The y-intercept implies a negative offset of ~20 ppmv. For trichloroethene, the regression line when both techniques were above the detection limit is given as FTIRS=(0.880.03)*GC-(910) with an R2 of 0.934. The ~12% negative bias noted in the slope is consistent with the accuracy associated with the analysis of the reference standard (see Table II). With few exceptions the two analysis techniques track each other quite well for 111-trichloroethane and trichloroethene. Correlation for 11-dichloroethene does not appear be good; however, if one considers the 15% positive bias for the GC-MS method (see Table 5-2) and the ~10% bias for the FTIRS, this result is not surprising.

The regression line for acetone when results for both the GC and FTIRS techniques are above their detection limits is FTIRS=(0.830.04)*GC-(03) with an R2 of 0.900. Examination of the overall data for acetone indicates a large number of false negatives for FTIRS analysis relative to the GC. Most alarming were the false negatives when the GC result was at 70-100 ppmv. Examination of the data one of these samples is interesting. For this sample, the GC indicated a concentration of 100 ppmv acetone and 1900 ppmv 111-trichloroethane. The FTIRS analysis indicated that acetone was <18 ppmv, however 1-butanol, 2-butanone, ethyl ether and 111-trichloroethane were at 101, 413, 95, and 1800 ppmv respectively. Because of the complexity of the sample spectrum, direct examination after 111-trichloroethane had been subtracted, could not rule out the presence of acetone or, confirm the presence of 1-butanol, 2-butanone, or ethyl ether because the presence of an unidentified compound present that has spectral characteristics similar to alcohols and/or ketones. As many as four other compounds were known to coelute with acetone in the GC-FID method. The compounds that are known to coelute with acetone are freon 113, ethanol, carbon disulfide and dimethoxymethane. Because of the high concentration of 111-trichloroethane, a very large dilution was required for the second analysis by GC-MS which raised the detection limits. However, reanalysis of the stored GC-MS data confirmed acetone. To determine the final dilution factor for the GC-MS analysis, a screening GC-FID is run at ~3.5x dilution of the sample. This analysis indicated a variety of peaks that were not identified. The FTIRS analysis was performed with no dilution of the sample.

Correlation between the FTIRS and GC analyses for toluene indicates a significant number of false or severely positively biased results for the FTIRS method. The main absorption band for toluene is interfered with severely by 111-trichloroethane and CO2. The magnitude of spectral residuals for the toluene method could be directly correlated to the positively biased toluene results and the presence of very high CO2 concentrations. Because the CO2 concentration was so high, nonlinear absorption of light affected this region of the spectrum. Because toluene is also found in nearly all of the actual headspace samples at low concentrations, toluene was likely positively identified but the quantitation was likely biased because the calibration for toluene is linear, however the absorbance is now nonlinear due to the excessive CO2 and spectral residual resulted. The CO2 was likely correctly compensated

for since the series of CO2 spectra in the calibration set were designed to identify the nonlinear behavior associated with high concentrations. The overall analysis results of the FTIRS compared to the GC methods is shown qualitatively in Table III as the number of true and false identifications are given along with the calculated total error rates ((false positives + false negatives)/total analyses), sensitivities and selectivities. The overall total error rate is generally in the 8-9% range with only 1% of these errors being false negatives. The specificity indicates that the FTIRS will discriminate against the analytes that are not present ~92% of the time. Likewise, the FTIRS method will identify the presence of the components ~90% of the time. The results are somewhat better when the methane, trimethylamine and hydrocarbon results are dropped. Trimethylamine and hydrocarbons are tentatively identified compounds in the GC/GC-MS methods and may not have been reported if their concentrations were low. Methane was only seen in the reference standards and the GC method failed to identify it even though the concentration was above the detection limit. The sensitivities listed should be viewed with caution, since the results may be biased by the low number of true positive for most analytes.

Table III

Examination of Table III indicates a large number of the cis-12-dichloroethene analysis results were false positives. The detection limits for cis-12-dichloroethene in the samples was usually in the ~12 ppmv. Of the false positives, 91% were <20 ppmv and all were less than 27. Most compounds, false positives could be similarly categorized. The major exceptions have been noted in the previous discussions. For example, many of the false positives for ethyl ether and 1-butanol could be due to the interferences which caused the acetone to be a false negative as described above. At two times the detection limits, i.e. a practical quantitation limit, the total error rates drops to <1%, sensitivities are ~95% and selectivities are ~98%.

Among of the quality assurance objectives for the analysis of gas samples for the TWCP is the analysis of blind audit samples as part of the PDP. (11) These blind samples are distributed, analyzed, and evaluated every 263 weeks. Performance is evaluated with blanks where no target compounds exceeding 50% of the PRQL, precision within 25%, accuracy within 30% and qualitative identification of non target analytes. In the most recent series of PDP samples, the FTIRS scored a 93% for the critical target compounds and 81% overall for the target compounds. The overall score was considered a pass and the critical target compound score was considered a conditional pass as a score of 95% is considered optimal. The major problem that may have caused this somewhat low score was that for some of the samples, the target concentrations were at or near the FTIRS detection limit and therefore may have slightly missed the accuracy or precision requirement. The only exception to this was for 1,2-dichloroethane which was ~35% negatively biased. This was the primary error that caused the score for the critical target compounds to be <95%.

CONCLUSIONS

Based upon the work presented in this paper, the analysis of waste drum headspace for VOCs with FTIRS appears to be quite feasible. Qualitative and quantitative determinations of VOCs with FTIRS are generally well within the requirements of the TWCP program, i.e. 30% accuracy and 25% precision. Long term precision of the technique and instrumentation is very good as it is generally <10%. The technique does appear to be

slightly negatively biased however. The reason for this bias has not been positively identified; but, maybe, in part, be due to the number of factors necessary for the calibration to adequately model the component of interest. In any case, the present systems with the 20 cm pathlength cell and DTGS detector appear to be quite capable of quantitative analysis of the 29 target VOCs, the C1-C3 hydrocarbons, and 6 known interferences in 3-6 minutes. The concentration range covered, depending upon the analyte, is from low ppmv to several percent. The use of longer pathlengths and more sensitive MCT detectors will reduce the detection limits and speed the analysis; however, there may be a sacrifice due to increased interference from low concentration unknown compounds in the samples and in the concentration range that can be covered. The calibration sets have been used on at least three different instruments appear and they do appear to be "universal", provided that the frequency accuracy of the instrument is within tolerance.

ABSTRACT

The Safety Analysis Report for the TRUPACT-II Shipping Package (Transuranic Package Transporter-II (TRUPACT-II) SARP) set limits for gas generation rates, wattage limits, and flammable volatile organic compound (VOC) concentrations in transuranic (TRU) waste containers that would be shipped to the Waste Isolation Pilot Plant (WIPP). Based on existing headspace gas data for drums stored at the Idaho National Engineering Laboratory (INEL) and the Rocky Flats Environmental Technology Site (RFETS), over 30 percent of the contact-handled TRU waste drums contain flammable VOC concentrations greater than the limit. Additional requirement(s) may be imposed for emplacement of waste in the WIPP facility. The conditional no-migration determination (NMD) for the test phase of the facility required that flame tests be performed if significant levels of flammable VOCs were present in TRU waste containers. This paper describes an approach for investigating the potential flammability of TRU waste drums, which may increase the allowable concentrations of flammable VOCs. A flammability assessment methodology is presented that could allow more drums to be shipped to WIPP without treatment or repackaging and reduce the need for flame testing on drums. The approach includes experimental work to determine mixture lower explosive limits (MLEL) for the types of gas mixtures observed in TRU waste, a model for predicting the MLEL for mixtures of VOCs, hydrogen, and methane, and revised screening limits for total flammable VOC concentrations and concentrations of hydrogen and methane using existing drum headspace gas data and the model predictions.

INTRODUCTION

The U. S. Department of Energy (DOE) intends to begin operation of the Waste Isolation Pilot Plant (WIPP) beginning in 1998. Waste characterization requirements for shipping transuranic (TRU) waste from DOE sites to the WIPP facility are set forth in the Safety Analysis Report for the TRUPACT-II Shipping Package (Transuranic Package Transporter-II (TRUPACT-II) SARP) (NRC 1994). The TRUPACT-II SARP, in evaluating gas generation rates and potential flammability of the wastes, requires that gas phase concentrations of flammable volatile organic compounds (VOCs) not exceed 500 ppmv and the hydrogen and methane concentration not exceed 5 percent. Additional requirement(s) may be imposed for emplacement of waste in the WIPP facility. In the conditional no-migration determination (NMD) for the test phase of the WIPP facility, the U.S. Environmental Protection Agency (EPA) required that each waste container emplaced underground at the WIPP facility have no layer of confinement containing either flammable mixtures of gases or mixtures of gases that could become flammable when mixed with air. The conditional

NMD required that flame tests be performed if significant levels of flammable VOCs (500 ppmv) were present in TRU waste containers. Based on existing drum headspace gas data for over 800 drums stored at the Idaho National Engineering Laboratory (INEL) and the Rocky Flats Environmental Technology Site (RFETS), over 30 percent of the contact-handled TRU waste drums contain greater than 500 ppmv of potentially flammable VOCs. Under current requirements, these drums cannot be shipped. Moreover, the volume of drums that are in accessible storage that can be shipped will be significantly reduced under these requirements and near-term shipment schedules will be impacted. However, based on the existing drum data and preliminary calculations, it is anticipated that only 10 percent of the drums are potentially flammable and 90 percent are safely shippable without treatment or repackaging. Costs associated with treatment or repackaging the waste for shipment will be substantial and flame testing, if required, will also have cost impacts. Preparing the waste for shipment and flame testing will both impact the scheduling of shipments to the WIPP facility. The flammability assessment methodology given in this paper is intended to increase the allowable concentrations of potentially flammable VOCs and thereby allow more drums to be shipped without treatment or repackaging, reduce the number of drums requiring flame testing, reduce costs, and minimize delays in waste shipments.

This paper describes an approach that includes investigating the potential flammability of TRU waste drums, increasing the allowable concentrations of flammable VOCs, and performing flammability assessments on drums. Estimates based on existing drum data indicate that when the proposed methodology is implemented, the number of drums that can be shipped without treatment or repackaging would be substantially increased. Because the methodology incorporates experimental data, validated predictive modeling of mixture lower explosive limits (MLEL) for the drums, and conservative screening of flammable gas concentrations, it is technically defensible and appropriate. The methodology takes into account the presence of all flammable gases in the wastes in determining acceptable screening limits for flammable gas concentrations in drums. Specifically, hydrogen and methane are considered in addition to VOCs.

Both empirical and theoretical models for predicting MLELs are considered. A model will be selected for use in flammability assessments that performs well relative to experimental data, adequately accounts for gas mixture compositions in drums, and demonstrates an acceptable level of conservatism. Screening limits are based on population statistics for flammable gas concentrations in the innermost layers of confinement in the drums, including the model-based maximum permissible hydrogen and methane concentration (MPHMC). The methodology for evaluating drums involves comparisons with screening limits, comparisons with less conservative drum-specific limits as necessary, and flame testing for drums that exceed these limits.

The MPHMC will be used to establish maximum allowable generation rates for hydrogen and methane gas. These rates, which will be calculated using the TRUPACT-II SARP methodology, must be determined because total concentrations of flammable VOCs may exceed the limit of 500 ppmv previously used in determining gas generation rates. The results could support preparation of an application to the Nuclear Regulatory Commission (NRC) to modify the current restrictive limits. This may

ultimately allow more waste to be shipped to the WIPP facility without repackaging or treatment.

This paper provides the technical basis for and description of the flammability assessment methodology as developed to date. First, a description of the testing to determine MLELs of TRU waste container gas mixtures is provided. Models that have been identified for assessing mixture flammability are described next. Following this, a description of the approach for determining the screening levels based on statistical analyses is presented. Finally, the steps of the flammability assessment methodology are given.

FLAMMABILITY TESTING PROGRAM

Considerable experimental data exist on the flammability of gas mixtures found in industrial and mining applications, such as mixtures comprised of hydrogen, methane, carbon monoxide, carbon dioxide, nitrogen, and oxygen. However, no experimental data are available for the types of gas mixtures observed in TRU waste containers. The objective of the flammability testing is to experimentally determine the lower explosive limit (LEL) for various TRU waste container gas mixtures.

The gas mixtures to be evaluated are composed of flammable and nonflammable VOCs listed in the Transuranic Waste Characterization Quality Assurance Program Plan (DOE 1995a) and hydrogen. To facilitate the experimental design, the flammable VOCs have been organized into functional and LEL groups. Functional groups for flammable VOCs are groups of VOCs with similar chemical structural characteristics. LEL groups for flammable VOCs are groups of VOCs with LELs that fall within a prescribed range of LEL values. The functional groups and associated functional group numbers (FGN) to be considered are aromatics (FGN = 1), ketones (FGN = 2), alcohols (FGN = 3), and alkanes/alkenes (FGN = 4). The LEL ranges and associated LEL group numbers (LGN) to be considered are 0.9%-1.3% (LGN = 1), 1.4%-2.6% (LGN = 2), and 5.6%-6.7% (LGN = 3). There is a general correlation between functional groups and groups based on LEL. That is, VOCs of a functional group tend to have LELs in a particular range. Table I summarizes flammable VOCs by functional and LEL groups.

Table I

The flammability testing will be done in two phases and will be based on a factorial experimental design that utilizes the LEL groupings. The factors are the presence or absence of each of three flammable VOC LEL groups in the mixture, the presence or absence of hydrogen in the mixture, and the presence or absence of nonflammable VOCs in the mixture. The objective of the first phase is to provide the necessary data to develop an empirical equation that expresses the flammable gas MLEL as a function of the concentration of each of the factors (i.e., concentrations of each of the three flammable VOC LEL groups, the concentration of hydrogen, and the concentration of nonflammable VOCs). The first phase will involve the testing of approximately 40 mixtures at ambient room temperatures (i.e., approximately 70F). These mixtures will be composed of varying ratios of 1,1-dichloroethane, methyl ethyl ketone, toluene, hydrogen, and carbon tetrachloride.

The objective of the second phase is to investigate the effects of VOC substitution within a group and to evaluate the effects of concentration on the predicted LEL. The second phase will involve the testing of an additional 30 mixtures, half of which would be tested at an elevated temperature of 146F. The second phase will also involve additional

chemicals, possibly acetone, benzene, cyclohexane, 1,1-dichloroethene, cis-1,2-dichloroethene, methanol, or methane, depending on the results of the first phase.

The results of the flammability testing will provide the empirical data needed to develop an empirical model for predicting flammable limits for mixtures of flammable gases in TRU waste containers. The results will also be used to evaluate the performance and adequacy of other predictive models.

MODELS FOR ASSESSING MIXTURE FLAMMABILITY

Four models for assessing mixture flammability have been identified through literature searches and discussions with flammability experts. The literature search identified documents that pertain to flammability limits and predictive methods. The search identified three theoretical models that are applicable to the problem. An empirical approach to modeling MLELs that would directly utilize experimental results was also identified. The four models being considered are an empirical model, the Le Chatelier rule, the group contribution method, and the adiabatic flame temperature method.

Empirical Model

The data obtained from the flammability testing will be used to develop an empirical model for predicting lower flammable limits for mixtures of VOCs and flammable inorganic gases in TRU waste containers. The empirical model is an equation that expresses the flammable gas MLEL as a function of the concentrations of each compound tested. The coefficients in the equation are obtained through standard least-squares statistical techniques and can be tested for their significant contribution towards predicting the MLEL. Experimental errors can be used to determine confidence limits for the predictions.

Le Chatelier's Rule

The Le Chatelier rule is an empirical equation developed by Le Chatelier in the late 19th century that enables the flammability limits of a mixture to be calculated if the flammability limits of individual components of a mixture are known. The effects of a few inert or nonflammable compounds (i.e., carbon dioxide and nitrogen) on the MLEL can be evaluated using a graphical method. The Le Chatelier rule has been tested for many mixtures that are important in transportation, industrial applications, and mining.

Group Contribution Method

The group contribution method provides an estimate of the flammability limits of a mixture based on knowledge of the chemical structure of each flammable compound in the mixture. The method does not account for the presence of inert (i.e., nonflammable) compounds that may be present in the mixture. Several group contribution methods have been proposed by various researchers (Shebeko et al. 1983; Season 1991; ASTM 1994; AIChE 1994) for estimating the LEL of individual compounds. However, no group contribution method has been proposed for mixtures of flammable gases. Based on an extension of the method for estimating the LEL of pure compounds (Procedure B) of the American Institute of Chemical Engineers (AIChE) Data Prediction Manual (AIChE 1994), the LEL was estimated for each of the gas mixtures and compared with the corresponding LEL estimated using the Le Chatelier rule. The absolute average error between the two methods was approximately 2 percent, with the group contribution method predicting a higher LEL in almost all cases.

Adiabatic Flame Temperature Method

The adiabatic flame temperature method is based on calculating and comparing the adiabatic flame temperature of a potentially flammable gas mixture with the critical or limiting adiabatic flame temperature. In the event of an explosion, energy is released by the combustion of the flammable compounds. Initially, the energy is absorbed by (1) unreacted reactants, (2) the combustion products, and (3) inert or nonflammable gases. Eventually, however, the energy will be dissipated from the system by various heat transfer processes. If a flammable gas mixture explodes in an adiabatic system (one in which there is no transfer of heat to or from the system), then it is possible to calculate an adiabatic flame temperature that corresponds to the temperature of the system after the explosion. The minimum temperature at which a flame can be sustained is referred to as the critical or limiting adiabatic flame temperature.

A number of computer codes are available to perform the complex thermodynamic chemical equilibrium calculations, including the American Society of Testing and Materials (ASTM) CHEETAH code (ASTM 1994), the National Aeronautic and Space Administration (NASA) Lewis Research Center CET93/CETPC code (McBride et al. 1994), the Lawrence Livermore National Laboratory (LLNL) CHEETAH code (Fried 1995), the University of Arizona CHEMEQ code (Wendt 1993), and the NASA CET93/CETPC code (NFPA 1988). If the adiabatic flame temperature of a potentially flammable gas mixture calculated by the code is above the critical or limiting flame temperature, then the mixture is flammable.

DETERMINING SCREENING LIMITS FOR FLAMMABLE GASES

A predictive model that performs well relative to experimental data, adequately accounts for gas mixture compositions in drums, and demonstrates an acceptable level of conservatism will be selected for use in determining drum-specific MLELs. The model will be selected from the models previously discussed. The MLELs predicted using the model will account for the presence of flammable VOCs, hydrogen, and methane in the drums. Because all flammable gases are included in the MLELs, the maximum concentration of hydrogen and methane that can be tolerated without the gas phase mixture becoming potentially flammable is the difference between the MLEL and the total concentration of flammable VOCs. This difference is the MPHMC.

To date, over 500 drums stored at the INEL and the RFETS have been sampled and analyzed for a specific suite of VOCs, hydrogen, and methane under the existing Transuranic Waste Characterization Program (TWCP). The samples were obtained from headspace gases under the drum lid with the rigid drum liner punctured. Additional drum sample analyses that are currently being gathered under the TWCP will be used in finalizing the flammability assessment methodology. The analyses will be used in determining screening limits for flammable gases.

The process for determining the screening limits for flammable gases is summarized in Fig. 1. First, the experimental and modeling work must be completed. The results will be used to choose a method for predicting MLELs. The chosen method will be used to obtain drum-specific MLELs using predicted innermost confinement layer headspace concentrations for existing drum data. The MLELs and the sums of flammable VOC innermost confinement layer concentrations will be used to compute drum-specific MPHMCs for existing drum data. Finally, screening values will be statistically determined for the sum of flammable VOCs and for MPHMCs.

Fig. 1

METHODOLOGY FOR ASSESSING FLAMMABILITY OF GAS MIXTURES IN TRU WASTE

Flammability assessments for individual drums are comprised of sequential evaluations, as necessary. The methodology consists of the following steps in evaluating individual waste drums for flammability (see Fig. 2):

1. Analyze drum headspace gas.
2. Predict innermost-layer headspace concentrations of flammable VOCs, hydrogen, and methane.
3. Sum innermost-layer concentrations of flammable VOCs and sum innermost-layer concentrations of hydrogen and methane.
4. Compare the flammable VOC sum with the flammable VOC screening limit and the hydrogen and methane sum to the MPHMC screening limit. If the both sums are below their associated limits, the drum may be shipped; if not, then go to step 5.
5. Compute the drum-specific MLEL, drum-specific MPHMC, and the sum of innermost concentrations of flammable VOCs, hydrogen, and methane.
6. Compare the flammable VOC, hydrogen, and methane sum with the drum-specific MLEL and compare the hydrogen and methane sum with the drum-specific MPHMC. If both sums are below the drum-specific limits, the drum may be shipped.
7. If at least one of the sums exceeds the respective limit, perform a flame test that simulates the gas mixture. If the flame test indicates that the mixture is not flammable, the drum may be shipped; otherwise, the waste must be either repackaged and reevaluated or another option must be taken, such as waste treatment.

Fig. 2

SUMMARY

The methodology may substantially increase permissible concentrations of flammable VOCs and consequently, the number of drums that can be shipped to the WIPP facility without treatment or repackaging. This increase would alleviate schedule impacts associated with near-term shipment of drums in accessible storage. The increase would also reduce schedule and cost impacts associated with waste repackaging or treatment. Furthermore, because the methodology incorporates experimental data, validated predictive modeling of actual drum lower explosive limits, and conservative screening of flammable gas concentrations, it is technically defensible and appropriate.

This work will be integrated with several other ongoing programs. Specifically, the results of the drum headspace gas sampling analysis being performed by the INEL and the RFETS under the TWCP will be used to develop the flammability screening limits. The results of the TRUPACT-II Gas Generation Testing Program and the TRUPACT-II Matrix Depletion Program will be used to establish new wattage limits by waste type. The TRUPACT-II compliance documentation will have to be revised to reflect the revised container wattage limits. Based on the revised wattage limits and the new methodology for determining flammability, an application for an amendment to the TRUPACT-II Certificate of Compliance will be submitted to the NRC for approval.

ABSTRACT
One of the aspects of the problem connected with the treatment of heterogeneous wastes accumulated over the period of the operation of a radiochemical plutonium-producing enterprise is considered. The final goal of the work is the evacuation of radioactive wastes from the storage tanks and the decontamination of the wastes by removing long-lived radionuclides from the solid phase. The assessment of the phase composition of the precipitates is made using an X-ray powder diffraction analysis. The results obtained indicate that during the storage time of several decades, the wastes have undergone significant transformations.

INTRODUCTION

At present, the amount of various radioactive wastes, for which no decontamination or treatment technologies have been developed previously, is very large. As a rule, radioactive pulps were directed into tanks for a temporary storage. These tanks have a limited service life. In addition, the problems of treatment of the radioactive sludge (bottom residue) formed in surface storage reservoirs for liquid radwastes and pools for the storage and handling of fuel elements, remain unsolved.

The development of the strategy of treatment of these wastes involves both technological and ecological aspects, because the pulps and the sludges contain a large amount of long-lived radionuclides, primarily \7a\1-emitters. In addition, any method of treatment of radwastes should allow for the technological capabilities of any specific plant, the economic characteristics of the process, and accepted safety standards. The determination of the most efficient method of treatment will be possible, if true information about the state of the object to be studied is available. For the pulps, the data on the phase composition of the macrocomponents and the chemical forms of the existence of radionuclides by the time of the beginning of waste treatment are required. The information obtained thus far indicates that the precipitates found in the pulps and sludges undergo structural transformations involving both macro- and microcomponents.

This work is one of the stages of the development of a chemical technology of treatment of heterogeneous wastes and is devoted to a study of the compositions of the phases formed during a long-term storage of precipitates in tanks.

TECHNICAL DISCUSSION

Table I shows the results of the chemical analysis of two sludge samples taken from different tanks with a volume of 3000 m3, made of ferroconcrete and having the form of cylinders with diameter 12 m and height 30 m. These tanks are clad with 4-mm thick stainless steel and are installed in a rocky soil. Over 30 years, the first tank (sample 1) was used for the storage of mainly ferrocyanide precipitates, and second tank (sample 2) was used for the storage of hydroxide precipitates (iron hydroxides, aluminum, silica gel, etc.). Prior to analysis the samples were compacted by a 3-day setting.

Table I

The sludge samples (200 cm3) were taken through the hatch in the upper part of the tank, using a special sample-taking device.

As follows from the results of Table I, the solid phase of the sludges is characterized by a comparatively large concentration of a-emitting elements (uranium and plutonium) and a significant level of b-and g-activity.

The samples of the precipitates designed for X-ray powder diffraction studies were washed 8 - 10 times with hot distilled water, the samples were centrifuged, and the liquid phase containing water-soluble impurities was decanted. The solid phase was dried in air. Note that, as result of this washing, virtually all uranium was removed from the solid phase, which was confirmed by the spectral analysis data. The concentration of water-soluble impurities in the samples was monitored using an X-ray diffraction analysis. For this purpose, the X-ray diffraction patterns of the precipitates formed after the evaporation of the decantates were recorded. These X-ray diffraction patterns were compared with the X-ray diffraction patterns of the washed sludge samples. The latter did not show reflections characteristic of water-soluble compounds.

Table II shows the sets of interplane distances for the sludge samples investigated. The X-ray diffraction patterns of the sludges have a complicated character and indicate the presence of several crystalline phases in the precipitate. All X-ray diffraction patterns show an intense halo in the low-angle range, which is characteristic of amorphous phases.

Table II

The X-ray diffraction pattern of sample 1 indicates the absence of crystalline ferrocyanide phases in the precipitates.

On the basis of the chemical composition of the solid phases and the conditions of their storage (long-term action of high temperatures and fields of ionizing radiation), a phase possessing the set of interplane distances characteristic of the hematite mineral (a-Fe2O3) was identified (1). Note that this phase is present in the sludge samples taken from different tanks. The color of natural hematite changes from red-brown to black. The color of real sludges also changes in the same manner. Theoretically, the composition of the hematite mineral is described by the formula Fe2O3 powever, natural hematite always contains impurities. The presence of impurities in the hematite structure leads to a change in the crystal lattice parameters, which is observed in our case.

In addition, the X-ray diffraction pattern also shows the set of interplane distances consistent with the crystal structure of the takovite mineral (2). This mineral belongs to the group of hydrotalcite and has composition Ni5Al4O2(OH)10'6H2O. The takovite phase disappeared after the treatment of sample 1 with a solution of hydrochloric acid.

The set of interplane distances characteristic of hematite was identified for sample 2 after the subtraction of the reflections characteristic of the kyanite or disthene mineral (3). This mineral (Al2SiO5) belongs to the class of silicates. The reflection intensities indicate the prevalence of the hematite phase in the precipitate.

Table III

The X-ray powder diffraction, IR spectroscopic, chemical, and radiometric analyses that the sludges do not contain the phases that were initially disposed into the storage tanks. As a result of a long-term action of fields of ionizing radiation and, as a consequence, increased temperatures, the chemical forms found in this heterogeneous system underwent transformations. This was accompanied by the formation of M-OH-M and M-O-M bonds, the decomposition of the initial crystalline phases, and the formation of new crystalline phases.

The processes of the transformation of the solid phases are , to a certain extent, similar to those that take place during the formation of hydrogeneous-mineral deposits in a geological medium.

The transformation of the macrophase was accompanied by the transformation of the chemical forms of long-lived radionuclides, which is particularly important for plutonium present in both ionic and colloidal forms. Thus, the formation of mixed phases with the macrocomponents of the precipitate and an increase in the crystallinity of the plutonium hydroxide species were observed. The indirect evidence that similar processes do take place are the results of the experiments on the solvent extraction of plutonium with nitric acid containing hydroquinone (4). In the presence of hydroquinone, a simultaneous increase in the silicon and plutonium concentrations in the liquid phase was observed. Experiments on model systems were carried out, in order to refine the character of the process and to determine the effect of iron (II) ions.

The results of the study of the system composed of a mixture of silica gel and plutonium hydroxide after heating for 200 hours at 100o confirmed the assumption about a possible interaction between hydroxide, leading to the formation of a common phase, in the course of aging. Upon the subsequent treatment of the resulting precipitate with a nitric acid

solution of hydroquinone, Pu(IV) was reduced to Pu(III), plutonium compounds with silicon decomposed, and these elements passed to solution. The redox processes, which took place in the pulps, led to the formation of new phases with crystal structures of minerals such as hematite, kyanite etc. The properties of these phases in these heterogeneous systems somewhat differ from those of pure phases of the minerals identified. The chemical stabilities of these phases were determined, and methods for the selective dissolution of individual phases were developed.

CONCLUSIONS

The experiments on modeling the processes occurring during a long-term storage of sludges in tanks allowed us to determine the behavior of plutonium fission products and various valent forms of plutonium, including colloidal species, during the transformation of individual phases of the macrocomponents in these heterogeneous systems.

Based on these data, we developed a technology of the chemical decontamination of the sludges. With a minimal dissolution of the macrophase, this technology allows a high-efficiency removal of long-lived radionuclides from the sludges. As a result, the amount of secondary radwastes, both liquid and solid, decreases. The information about the structures of the precipitates at different stages of their treatment helps to optimize the process of the subsequent solidification of these phases.

PRIMARY STUDY OF SEPARATION OF CESIUM FROM WASTE SOLUTION OF SPENT FUEL IN CHEMICAL PREDISPOSAL WITH CRYSTAL AMMONIUM MOLYBDPHOSPHATE (AMP) BEFORE VITRIFICATION

Weng Haomin
Tian Guoxing
Beijing Normal University
Division of Radiochemistry
Beijing 100875 China

ABSTRACT

Ammonium Molybdphosphate(AMP) is one of significant inorganic exchangers for separation of cesium from high level acid liquid waste (HLLW) (1,2), but the formerly prepared AMP were microcrystals, which was very difficult to apply in a column test. For the first time, we obtained granular crystal of AMP by taking advantage of equilibrium between PO43- and P2O74- in acid solution. The static ion exchange capacity for cesium was 0.63mmol/g and the distribution coefficient Kd was 350ml/g in 1 mol/l HNO3. The dynamic ion exchange capacity for cesium was 0.55mmol/g in simulated HLLW. After absorbing 2106 Gy dose from 60Co, the ion exchange properties did not change.The results of experiments indicated granular

AMP was one of the best chemical pretreatment material before vitrifying HLLW.

INTRODUCTION

In reprocessing a large amount of HLLW was produced. The Chinese HLLW which came from Purex process is a concentrated acid solution which contains fission products and has a very high salt content, especially nonradioactive nuclides such as Na, Al, Fe, Ni, and Cr. After a period of time in storage, the short lived nuclides decayed. The radioactivity comes from the long half-life nuclides in which the activity of 137Cs and 90Sr is 1.31012 and 9.31011 Bq/L. Table I gives the main composition of Chinese HLLW in a typical storage tank.

There are two ways for disposing of this type of HLLW, chemical treatment and vitrification. Chemical treatment could be divided into two steps. The first step is separating cesium and strontium. The second step is extracting transuranics from HLLW (3). After chemical treatment, the activity of the HLLW will be reduced 103 or more. The waste becomes a lower level radioactive waste stream that could be solidified in cement and disposed of in near surface with an engineered barrier. The TRU elements and 99Tc, which is only about 1% of salt content of original Chinese HLLW, can be transmuted to either stable or short half-life nuclides. They can also be incorporated into a glass matrix and disposed into a deep geologic repository. The separated 137Cs and 90Sr could be beneficially used or encapsulated for near surface storage.

Table I

The characteristic of chemical treatment are:

- the radioactive nuclides can be recovered and reused
- disposal processes such as ion exchange and extraction is easier
- the disposal cost is lower

The research work of inorganic ion exchanger for separating cesium-137 and strontium-90 was very extensive and mature. Some inorganic ion exchangers have good selectivity. When the waste solution is passed through the column, only cesium or strontium are absorbed. Although inorganic ion exchanger is an ideal material for recovering cesium and strontium, applying them is very difficult in a column test because they have some drawbacks and most of them are microcrystals. We synthesized granular crystals of AMP for recovering cesium, which solved the problem successfully. The preparation and behavior of granular AMP is described in this paper.

EXPERIMENT

Synthesis of AMP

Potassium pyrophosphate solution (0.025 mol/l in 1 mol/LHNO3) and ammonium molybdate solution(0.2 mol/l in 1 mol/LHNO3) are mixed at room temperature, in a volume ratio of 1:1. Aging about two weeks, yellow crystal precipitated and were separated with filter and dried at room temperature. After crushing up and sifting this crystal, the sample of AMP was obtained.

Analysis Composition and Structure of AMP

The content of NH4+ in sample was determined by decomposing NH4+ from AMP with 10% Sodium hydroxide solution and changing NH4+ to NH3, which was absorbed by standard sulfuric acid, then titrating this acid solution with standard alkali. The content of phosphor and molybdenum was determined by spectrophotometric method.

The structure analysis of AMP was determined by FT-IR Spectrometry (Nicolet 170SX U.S.A.), X-ray diffraction (Rigacu DMAX-2000 Japan), and Electron-microscope (T-605 Japan).

Determination of Ion Exchange Behavior of AMP Crystal

Took 0.1 g AMP and 20 ml 0.005 mol/l cesium or various ion nitrate (in 1 mol/l HNO_3) in small bottle, and shaked in thermostat at 20C. Determining the concentration of cesium in the solution at different time obtained the equilibrium curve and distribution coefficient Kd and static ion exchange capacity Q. The Kd and Q value are calculated by the following formula:

Eq. 1

Eq. 2

C0, C: concentration of original and equilibrium solution.

V: volume of equilibrium solution(ml).

M: weight of exchanger(g).

1.0g AMP was put in a column (diameter 0.36 cm, h:d is 4), operating temperature was 20C, flow rate was 1BV/hr. The feed solution was simulated Chinese HLLW.

RESULTS AND DISCUSSION

Composition of AMP Sample

The analytical results of sample were compared with theoretical value of $(NH_4)_3PMo_{12}O_{40}4H_2O$ as Table II shows.

Table II

The composition of AMP sample was in accordance with the theoretical composition of $(NH_4)_3PMo_{12}O_{40}4H_2O$ within an acceptable error.

Structure Analysis of AMP Sample

The IR and X-ray diffraction analysis of samples were in accordance with standard literature illustrations of $(NH_4)_3PMo_{12}O_{40}4H_2O$. The figures are omitted in this paper.

Composition analysis and structure analysis confirmed the sample was $(NH_4)_3PMo_{12}O_{40}4H_2O$. From the electron microscope photo (Fig. 1), the sample was cubic crystal.

Fig. 1

The Ion Exchange Behavior of AMP Crystal

The equilibrium curve of cesium was measured by static method with sampling at different times as shown in Fig. 2.

Fig. 2

From the curve the ion exchange equilibrium time of cesium was about 24 hours. The static ion exchange capacity Q was 0.63 mol/g, distribution coefficient Kd was 350 ml/g. The Q and Kd of various ions was determined by static method. The concentration of these ion was measured with ICAP instrument. The results as following Table III.

Table III

In dynamic tests of AMP sample with simulated Chinese HLLW, the concentration in the effluent vs effluent volume V(ml) gave the breakthrough curve as in Fig. 3. From the curve, the 1% breakthrough capacity was 0.51 mmol/g, 50% breakthrough capacity was 0.55 mmol/g.

Fig. 3

The radiolytic stability of the sample was tested with ^{60}Co, no significant change in exchange properties occurred until a total dose of 2106 Gy was absorbed.

CONCLUSION AND APPLICATION

Both the crystal AMP and microcrystal AMP have same behavior of ion exchange.

Crystal AMP is a good material for column testing.

AMP column removal of cesium-137 from HLLW could be a predisposal step for vitrification.

The crystal AMP will be a good material as an addition to vitrification, if the loaded AMP column does not elute cesium-137 in the process.

THE NEPTUNIUM-PROBLEM: CORRELATION OF NP(IV), NP(V) AND NP(VI) WITH HNO2 IN NITRIC ACID SOLUTIONS - POSSIBLE ADJUSTMENT OF THE NEPTUNIUM-VALENCE-STATE IN AN ADVANCED PUREX-PROCESS FOR PARTITIONING AND TRANSMUTATION (P&T)

ABSTRACT

One of the mostly striking problems of modern reprocessing based on the PUREX-Process is the uncontrolled spread of neptunium over the different product streams of a reprocessing plant, which is due to the rather complicated redox chemistry of this actinide in nitric acid solutions. According to the ideas of P&T, a strategy has been developed of quantitatively directing the neptunium into the fission product waste stream from which it can be isolated together with other actinides in order to provide them for future transmutation. Realizing this strategy the neptunium must be prevented from being coextracted together with uranium and plutonium in the first extraction cycle of the PUREX-Process. For that purpose the feasibility of a complete redox conversion of the element to unextractable Np(V) has been theoretically and experimentally investigated. As a first approach the behavior of neptunium in nitric acid systems of different acidities has been studied in order to gain more information about the initial valence-state distribution of the element after the dissolution of spent nuclear fuel. According to the results of these studies the major part of neptunium (80-90%) is already present as Np(V) at the end of the dissolution process. Because of the obvious influence of nitrous acid on the neptunium valence state equilibrium, a complete redox conversion of the actinide seems to be possible by controlling the concentration of nitrous acid in nitric acid solutions. First attempts started with a valence state composition as estimated for the feed solution of the PUREX-Process. They arrived at Np(V)-conversion rates of more than 94%. Thereby a new method of

controlling the concentration of nitrous acid has been applied having the advantage of excluding the production of any secondary waste. In order to avoid a later rearrangement of the neptunium-valence-state-equilibrium several reducing reagents have been tested for their ability of stabilizing Np(V). Some rather promising results have been obtained on employing urea and hydrazine. In the presence of these reagents the Np(V)-percentage could be enhanced to nearly 100%.

All chemicals used to treat the aqueous waste solution correspond to the CHNO-principle. According to that an increase in secondary waste is avoided by the use of reagents that are completely incinerable, producing only non-toxic gases and solutions such as CO_2, N_2 and H_2O.

INTRODUCTION

Several years ago the idea of Partitioning and Transmutation (P&T) was born, with the purpose of minimizing the long term risk of nuclear waste by a selective separation of long lived isotopes,actinides and fission products, and their later destruction by irradiation (1). As an objective the supporters of this vision wanted to achieve a drastic reduction of the radiotoxicity of HLW having in mind the reduced public acceptance of its long term storage. Due to the restricted possibilities of separation techniques as well as irradiation technologies in the past, the idea of P&T seemed to fail. Thanks to the rapid development of modern science, e.g. new accelerator driven neutron sources attaining rather high neutron flux densities, P&T has gained new importance in recent years (2). Thus new P&T-programs have been launched in several countries of the nuclear community in order to investigate either the necessary chemical separation techniques or suitable irradiation assemblies. Referring to the problem of Partitioning, many flow sheets have been developed and sometimes tested in cold or hot runs proposing different separation methods for actinides and fission products (3). Most of them are based on conventional reprocessing suggesting a combined isolation of transuranic elements after a complete removal of uranium and plutonium from the spent fuel. As far as these proposals for the waste handling employ liquid-liquid-extraction as a separation means, they normally refer to the PUREX-Process. Until today this process has been successfully implemented in many countries in order to recover uranium and plutonium from spent nuclear fuel and to make them available for further fuel fabrication (4). The extracting reagent used is Tri-n-butyl-phosphate (TBP), an organophosphorous reagent that exhibits good extraction properties towards tetra- and hexavalent actinides in nitric acid solutions. Thus, a nearly quantitative recovery of uranium and plutonium can be achieved. Unfortunately there is one other actinide - neptunium - which exhibits a similar redox chemistry and therefore is also accumulated in the first decontamination cycle (4).

Neptunium is mainly generated from U-238 by neutron capture during irradiation of fuel elements in nuclear reactors. On dissolving the spent fuel in nitric acid at the head end of the reprocessing plant the neptunium, initially present as NpO_2, is partly oxidized and an equilibrium of three valence states is established including Np(IV), Np(V) and Np(VI) (5). The extraction behavior of these three oxidation states is quite different. With respect to the extraction properties of TBP as described above, Np(IV) and Np(VI) are removed together with uranium and plutonium from the feed solution of the PUREX-process. In contrast to that hardly any reagent exists which can separate Np(V) from aqueous solutions. As a result the neptunium spreads over the whole

PUREX-process being finally contained in the uranium- and the plutonium-fraction as well as in the fission product waste stream.
Fig. 1
Regarding the radiotoxicological long term risk caused by neptunium, this uncontrolled spread is unacceptable. According to the requirements of a safe nuclear waste management and meeting the idea of P&T it has to be the objective of any basic research work aiming at a controlled recovery of actinides and fission products from spent nuclear fuel to develop a strategy of advanced reprocessing which will include a defined routing for neptunium during the process. This defined routing can either mean a coextraction of the element together with uranium and plutonium in the first extraction cycle of the PUREX-process or its prior transfer to the waste from which it could then be isolated together with the other transuranium elements providing them for further transmutation. Referring to the process-handling as well as the production of secondary waste, the latter proposal seems to be more favorable and thus has been chosen as the objective of our research work since about two years now.
Due to the fact that the extraction behavior of neptunium towards TBP fundamentally depends on the valence-state in which the actinide is present in the feed solution of the PUREX-process, a method of treatment had to be found that allows to control the redox-chemistry of the element in nitric acid solutions. Thus a strategy was investigated facilitating a total transfer of neptunium to Np(V) and thus hindering it from being extracted by TBP in the first extraction cycle of the reprocessing plant. In order to realize this idea, the composition of the neptunium valence-state distribution as well as its dependence on several influencing factors in nitric acid solutions were determined.
ADJUSTMENT OF THE NEPTUNIUM VALENCE STATE EQUILIBRIUIM AT THE HEAD END
In the Absence of Plutonium
In order to gain more information about the valence-state equilibrium of neptunium in the feed solution of the PUREX-Process the behavior of the actinide in the end of the dissolution of spent nuclear fuel in nitric acid was studied. For simplifying the first theoretical approach the presence of plutonium and iron in the spent fuel was omitted.
At the head-end of a reprocessing plant the irradiated fuel elements are dissambled, shorn and subsequently dissolved in nitric acid of varying molarities (6-2M) under slightly boiling conditions. In the course of this procedure the uranium, initially present as uranium dioxide (U(IV)), is oxidized to uranyl (U(VI)), which forms a water soluble nitrate-complex:

$$2\ UO_2 + 6\ HNO_3 \rightarrow 2\ UO_2(NO_3)_2 + NO_2 + NO + 3\ H_2O \quad (1)$$

As it can be seen from Eq. 1, nitric oxide and nitrogen dioxide are formed in the course of this reaction. In spite of the major part of NOx being released from the solution, the gas will be partly dissolved in the nitric acid leading to the formation of nitrous acid. Like the uranium, the neptunium will also be oxidized during the dissolution process following a reaction (see Eq. 2) quite similar to Eq. 1.

$$2\ NpO_2 + 6\ HNO_3 \rightarrow 2\ NpO_2(NO_3)_2 + NO_2 + NO + 3\ H_2O \quad (2)$$

In contrast to the quite stable uranyl the analogous neptunyl is subjected to a steady reduction mainly depending on the acidity as well as the amount of nitrous acid in the aqueous solution. Thus a valence-state equilibrium of Np(IV), Np(V) and Np(VI) is established.

$$2\ NpO_2^+ + NO_3^- + 3\ H^+ \rightarrow 2\ NpO_2^{2+} + HNO_2 + H_2O \quad (3)$$

$$2\ NpO_2^+ + 4\ H^+ \rightarrow Np^{4+} + NpO_2^{2+} + 2\ H_2O \quad (4)$$

According to literature (5) equation (3) summarizes a rather complicated oxidation-reduction-mechanism, in which the nitrous acid reveals the role of a catalyst. The overall redox reaction is known to be much faster than the disproportionation of Np(V) (see Eq. 4), which will be significant only at higher acidities and elevated temperatures (5,7).

Thus, the scale of the Np(V)/Np(VI)-ratio at the end of the dissolution of the spent fuel can be estimated by focussing on Eq. 3. For that purpose the quantitative development of nitrous acid during the dissolution of uranium dioxide was recorded in some preceding simulation experiments. It was found to shift from about 5E-4 mol/l at the beginning to about 3E-3 mol/l at the end of the process. After cooling the concentration of nitrous acid was reduced again yielding finally about 5E-5 mol/l. This last figure is estimated to correspond to the molarity in the feed solution of the liquid-liquid extraction where the acidity is adjusted to about 2 mol/l. Derived from the equilibrium constant of Eq. 3 the Np(V)/Np(VI)-ratio was calculated. According to this calculation, the oxidation state distribution of neptunium at the end of the dissolution process should reveal a clear excess of Np(V).

In order to compare the theoretical approach with experimental results, experiments were carried out under the same conditions as present at the end of the dissolution process. Thus the concentration of nitric acid was adjusted to 2 mol/l. At the same time the amount of nitrous acid in the aqueous solution was controlled by the introduction of nitric oxide. The neptunium added to the reaction vessel initially consisted of pure Np(IV) as expected to be contained in the nuclear fuel (NpO_2). Samples were taken after certain periods of time and were analyzed for their neptunium valence state composition.

Table I

The results of these determinations are depicted in Table I. According to them a relatively quick development of a valence state equilibrium was observed which could not be surveyed within the time range necessary for the off-line determination of the neptunium oxidation states. As expected this equilibrium revealed a maximum in Np(V) whereas the Np(IV)-portion was drastically reduced. With respect to the obtained results the valence state distribution seemed to depend on the nitrous acid concentration as well as on the temperature. This became evident on comparing the distribution of oxidation states determined in the reaction vessel with and without heating. At elevated temperatures the oxidation and disproportionation of Np(V) was obviously accelerated yielding an increased percentage of Np(IV) and Np(VI) (see Eq. 4).

In the Presence of Plutonium

With plutonium and iron present in the real nuclear fuel, the redox chemistry of neptunium in the dissolver as well as in the feed solution of the PUREX-Process might be basically influenced. In order to investigate this influence the experiments as described under a) were repeated in the presence of iron which was used to simulate also the presence of plutonium due to their similar redox potentials. As can be seen from Table I the Np(V)-percentage increased obviously reaching about 92% after cooling. Simultaneously the amount of Np(IV) and Np(VI) was reduced to 1,05% and 7,2% respectively. This unexpected comproportionation may be explained as follows:

In high molar nitric acid solutions plutonium and iron are likely to be oxidized to higher oxidation states (Pu(IV) and Fe(III)). As reported in (7, 8) these ions will oxidize Np(IV) yielding Np(V).

$Np^{4+} + Pu^{4+} + 2H_2O \rightarrow NpO_2^{+} + Pu^{3+} + 4H^{+}$ (5)

$Np^{4+} + Fe^{3+} + 2 H_2O \rightarrow NpO_2^{+} + Fe^{2+} + 4H^{+}$ (6)

On the other hand the reduced species Pu(III) and Fe(II) might cause a reduction of Np(VI) (see Eq. 8).

$NpO_2^{2+} + Fe^{2+} + 2 H_2O \rightarrow NpO_2^{+} + Fe^{3+}$ (7)

Thus, finally the presence of plutonium and iron leads to a comproportionation and further increase in Np(V) in the aqueous solution.

NEPTUNIUM VALENCE STATE COMPROPORTIONATION

As it has been shown, the valence state equilibrium of neptunium in nitric acid solutions strongly depends on the amount of nitrous acid present. In solutions with an acidity of not more than 2-3M an excess of Np(V) is to be expected. This excess is even enhanced in the presence of iron and plutonium. Thus, the idea of a complete comproportionation of the neptunium valence states to Np(V) seems to be realizable by a temporal limited control of the concentration of nitrous acid.

Once a complete comproportionation has been achieved, a rearrangement of the neptunium valence state equilibrium has to be excluded. This can only be realized by the application of a reducing reagent which will prevent any Np(V) from being reoxidized to Np(VI). Therefore our further efforts followed two different objectives.

Np Valence State Comproportionation by Controlling the HNO_2-concentration

The comproportionation experiments were carried out under similar conditions as the studies of the neptunium redox-behavior during the dissolution of spent fuel. Therefore a certain amount of neptunium was dissolved in 2M nitric acid. The valence state composition in the solution was adjusted to the distribution estimated for the feed solution of the solvent extraction according to our preceding investigations. Nitric oxide was bubbled through the reaction vessel in order to generate nitrous acid. The concentration of nitrous acid was controlled by temperature as determined in some preceding cold runs. Samples were taken from the solution in certain time-intervals and were analyzed for their composition of the neptunium valence state distribution.

Table II

Generally speaking the valence state conversion of neptunium has been successful even though the obtained Np(V)-percentages were not totally satisfying as yet. As depicted in Table II the measured conversion-rates were in a range of 80-94% in Np(V) depending on both the temperature (amount of nitrous acid) and the reaction time. A decrease of the Np(V)-percentage with increasing temperature was obvious. This was due on the one hand to the lower molarity of nitrous acid in the reaction vessel and on the other hand to the kinetics of the disproportionation reaction Eq. 5. Referring to the valence state distribution as obtained after different periods of time a maximum of Np(V)-comproportionation seemed to be attained after 1h. With proceeding reaction time the Np(V)-percentage was reduced. This reduction was mainly caused by a steady rise in nitric acid in the reaction vessel with a continued introduction of nitric oxide.

$2 NO + O_2 \rightarrow 2 NO_2$ (8)

$2 NO_2 \rightarrow N_2O_4 \quad DH > O$ (9)

$N_2O_4 + H_2O \rightarrow HNO_2 + HNO_3$ (10)

As can be seen from the Eq. 8-10 the immediate oxidation of nitric oxide in the oxygen-containing aqueous solution forms nitrogen dioxide (see Eq. 8) which will partly dimerize to dinitrogen tetraoxide (see Eq. 9). In the presence of water, the dimer itself disproportionates to nitrous acid

as well as nitric acid (see Eq. 10) and thus leads to a higher acidity. Caused by this rise in acidity the oxidation (see Eq. 3) and the disproportionation of Np(V) also increase (see Eq. 4), predominantly resulting in the formation of more Np(VI). If higher conversion-rates of neptunium shall be obtained the increase in acidity has to be avoided. This could be achieved either on working at lower concentrations of nitric acid or on reducing the hydrolysis of dinitrogen tetraoxide by controlling the reaction temperature.

Np Valence State Stabilization After the Valence-State Adjustment

With respect to the preceding results the neptunium valence state equilibrium is probably to be rearranged even if a comproportionation of the actinide has been achieved. To exclude any further oxidation of Np(V) several organic and inorganic reagents have been tested for their ability to stabilize Np(V) in nitric acid solutions due to their reducing character. All reagents used were in good correspondence to the CHNO-principle which proposes to employ only those materials for the treatment of nuclear waste that are completely incinerable in order to avoid any increase in secondary waste. Substances meeting this requirement should therefore contain only carbon, hydrogen, nitrogen and oxygen in their chemical structure.

The experiments started with an initial Np(V)-percentage of about 96%. The molarity of the nitric acid was varied from 1 to 3M. After the addition of the reducing reagent the composition of the neptunium valence state equilibrium in the solution was determined after certain periods of time. The promising results for two reagents that have been successfully tested (urea and hydrazine) are shown in Table III.

Table III

As expected they reveal an obvious increase in the Np(V)-percentage (99,7% in the maximum) due to the reduction of Np(VI). A further formation of Np(IV) could not be observed. Possible mechanisms for the reactions of urea and hydrazine with Np(VI) are presented by Eq. 11 and Eq. 12.

$$CO(NH_2)_2 + 6\ NpO_2^{2+} + H_2O \rightarrow CO_2 + N_2 + 6\ NpO_2^{+} + 6\ H^{+} \quad (11)$$

$$N_2H_4 + 4\ NpO_2^{2+} \rightarrow 4\ NpO_2^{+} + N_2 + 4\ H^{+} \quad (12)$$

Evidence for these mechanisms has been given by the following observation: According to Eq. 11 and Eq. 12 the reduction of Np(VI) yields a plain decrease in pH. Thus, on the other hand, the reduction rate should decrease with rising acidity. By comparing the reduction rates obtained at different concentrations of nitric acid as revealed in Table III, this correlation seems to be proved.

CONCLUSION

With respect to our studies on the behavior of neptunium during the dissolution of spent nuclear fuel, the major part of the actinide will be present as Np(V) in the feed solution of the PUREX-Process. Thus, a complete conversion of the element to its unextractable pentavalence state seems to be possible by taking advantage of the close correlation between the neptunium valence state equilibrium and the nitrous acid formed in the aqueous solution. The conversion rates obtained in some preliminary tests attained a maximum Np(V)-percentage of 94,2%. Thus, the general feasibility of a neptunium comproportionation could be shown. A clear dependence of the valence state conversion on thermodynamic and kinetic influences makes us believe that an optimization of these results can be achieved in the future. Even if a quantitative formation of Np(V) has not been achievable yet due to the ambivalent character of nitrous

acid, this might be realized by the application of some reducing reagents which exhibit stabilizing as well as enhancing features towards Np(V) in nitric acid. The most promising results have been obtained by employing urea or hydrazine as a reductant yielding a Np(V)-percentage of nearly 100%.

Although a complete comproportionation of neptunium in the feed solution of the PUREX-Process seems to be possible, some further research work is still required as several questions have not yet been answered. One of the most important aspects in this context will be the influence of iron and plutonium in the real feed. According to our theoretical as well as experimental studies on the dissolution process, their presence will initially cause a larger amount of Np(V). But it has to be kept in mind that any manipulation of the neptunium valence state equilibrium will also effect the redox chemistry of these two elements. Especially the use of strongly reducing reagents could lead to a disadvantageous reduction of Pu(IV) to the unextractable Pu(III) as it is known for hydrazine (7). Thus the coextraction of uranium and plutonium in the first decontamination cycle of the liquid-liquid extraction would be disturbed. Furthermore the possibility of a later separation of neptunium from the HLW has to be investigated with respect to the final goal of P&T. Therefore an oxidation of the actinide is proposed, aiming at a complete conversion to the extractable species Np(VI).

ABSTRACT
As a result of former reprocessing operations, two types of high-level radioactive waste (HLW) were generated at the Western New York Nuclear Service Center (WNYNSC) located in West Valley, NY. These were plutonium uranium extraction (PUREX) waste and thorium extraction (THOREX) waste. In 1980, the West Valley Demonstration Project (WVDP) Act was passed authorizing the Department of Energy (DOE) to conduct a HLW management project at the WNYNSC. As part of the Act, the approximate two million liters of HLW generated are to be processed and solidified by vitrification.
As a result of vitrification operations, residual amounts of the HLW described above and cesium (Cs)-loaded zeolite, a high-activity ion exchange waste stream generated from vitrification pretreatment operations, will be present in underground carbon steel tanks located in an on-site Tank Farm. Research is currently being conducted at the Pacific Northwest National Laboratory (PNNL) on the use of oxalic acid, which has been proposed to facilitate the removal of residual amounts of these high-level and high-activity wastes.*
Laboratory-scale tests performed by PNNL have been used to determine the optimum conditions in terms of acid-to-waste ratio, contact time, and the temperature of acid. In addition, the effects of multiple contacts, long-term contacts, the presence of corrosion products, the lack of agitation, and the temperature of tank contents were evaluated. The objectives of this research are to maximize the removal of the residual wastes from the carbon steel tanks, minimize the dissolution of iron, minimize corrosion, and provide a feed that is compatible with the current vitrification waste form specification.
INTRODUCTION
Approximately two million liters of HLW were generated during 1966 - 1972 at a commercial nuclear fuel reprocessing plant located at the WNYNSC in West Valley, NY. The waste, which consisted of alkaline sludge, alkaline supernate, and acidic liquid, was placed into two tanks located on the site for storage.
The largest volume fraction of waste was generated during reprocessing of spent uranium fuel using the PUREX process. Waste from the PUREX process was neutralized with sodiumhydroxide (NaOH) for storage in a carbon steel tank designated 8D-2. Neutralization resulted in a precipitated hydroxide sludge that settled to the bottom of the tank and a supernatant salt solution. The acidic liquid originated from the processing of thorium (Th) fuel from the Indian Point I reactor using the THOREX process. This waste was stored in a stainless steel tank designated 8D-4. Additionally, Cs-loaded zeolite, a high-activity waste, was generated from the WVDP pretreatment operations, which used zeolite in an ion-exchange process

designed to remove radioactive cesium from liquid HLW. The ion exchange columns and the spent zeolite are stored in a carbon steel tank designated 8D-1.

In preparation for vitrification operations, the spent zeolite is being removed from Tank 8D-1 and transferred to Tank 8D-2. Residual Cs-loaded zeolite, however, will be left behind. As a result of vitrification operations, a residual mixture of PUREX waste, THOREX waste, and spent Cs-loaded zeolite will remain in Tank 8D-2. The decision to facilitate removal of residual wastes by eluting the radioactive Cs from zeolite and dissolving the sludge, which will result in a transfer of the radionuclides to the Vitrification Plant and a decrease in the radioactivity remaining in the tank, is being evaluated as part of the stabilization objectives for these tanks.

Oxalic acid has been studied as a decontamination reagent for nuclear reactors and equipment. It may also be used to elute Cs from zeolite and to dissolve sludge. Previous laboratory studies show that oxalic acid can be used to elute Cs from zeolite at a level of 88-90% over a period of 11 days when 0.8 molar (M) oxalic acid is added to zeolite at ~20 liters (L) acid/kilogram (kg) zeolite.** These studies have also found that a maximum of 66 weight % (wt%) of washed sludge can be dissolved using ~0.7 moles of oxalic acid per unit of washed sludge (equal to one liter of PUREX sludge and supernate plus THOREX precipitated waste). In addition, it has been reported that over 95% of the sludge from the Savannah River Plant's Tank 16H was dissolved using 8 wt% oxalic acid at 85C with agitation in a two-step dissolution process (50 hours per step) with an initial reagent-to-sludge volume of 20:1.

The purpose of this paper is to discuss the research that is being conducted at PNNL. The results from a series of experiments that vary the strength of oxalic acid, the number of contacts, and the duration of contacts will be discussed in terms of the following primary objectives: maximize the removal of HLW from the carbon steel tanks, minimize the dissolution of iron, minimize tank corrosion, and provide a feed that is compatible with the current vitrification waste form specification.

CESIUM ELUTION EXPERIMENTS

These Cs elution experiments were performed in 500 milliliter (ml) Pyrex reaction vessels, with ports for thermocouples, stir shafts, and sampling, as shown in Fig. 1. Nonradioactive Cs-loaded zeolite was placed in the bottom of the reaction vessel and covered with 10 M NaOH to simulate the basic environment in Tank 8D-1. The 8 wt% oxalic acid was then added. The vessel was sealed using vacuum grease and placed in a heating mantle with a temperature controller programmed to hold the temperature at 50C (unless otherwise noted), which is the expected temperature of the material in Tank 8D-1 . A stirring shaft was placed in each vessel and the contents of the vessel were agitated throughout the test period (unless otherwise noted) to simulate the effects of the mobilization pumps. Tests were run for 50 hours (unless otherwise noted) and sampling was performed at 2, 4, 20, 28, and 50 hours of contact time (unless otherwise noted). When sampling was being performed, agitation of the material in the vessel was stopped and the material was first allowed to settle for five minutes. After five minutes, a 5 ml sample was drawn from the supernate and analyzed by Inductively Coupled Plasma-Mass Spectroscopy (ICP-MS) for Cs content.

Fig. 1

Some of the Cs elution experiments performed included: 1) determination of optimum process conditions, 2) multiple contact tests, and 3) tests to determine the effects of additional conditions such as the presence of corrosion products and carbon steel coupons, no agitation, and the temperature of tank contents.

The determination of the optimum process conditions for Cs elution from zeolite involved six tests. The variables in this experiment were the ratio of oxalic acid to zeolite, the temperature of the acid, and the contact time.

The multiple contact experiment involved four tests. Using the optimum process conditions previously determined, Cs-loaded zeolite was contacted with fresh oxalic acid three times for two hours. Two-hour contact times were chosen because previous experiments indicated that the majority of the Cs was eluted after two hours. After each contact, a sample of approximately 5 ml of supernate was drawn from each reaction vessel for analysis and the rest of the supernate was removed from the vessel. Two types of tests were performed for this experiment, one involving a water rinse of the zeolite after each contact and one with no water rinse.

The effects of several additional conditions on Cs elution from zeolite at the optimum process conditions were also evaluated. The presence of corrosion products in Tank 8D-1 and their effect on Cs elution was examined by adding iron oxide (Fe2O3) as a simulant. An amount of Fe2O3 equivalent to 2400 kg of rust at the bottom of the tank was added to the vessel.

The effect of carbon steel coupons on Cs elution was examined. Two carbon steel coupons were pre-weighed and suspended inside the reaction vessel so that they were completely submerged in the oxalic acid. The pair of coupons used for this test were prepared from larger U-bend coupons from earlier West Valley Nuclear Services (WVNS) corrosion tests. One of the coupons, after being measured and weighed, was left "as received" with a rusted layer on the surface. The other coupon was cleaned in an inhibited acid cleaning solution to remove the rust layer. Once cleaned the "clean" coupon was measured and weighed. When the test was complete, the coupons were removed from the vessel, rinsed in deionized water, dried at room temperature, and then re-weighed to determine weight loss and estimate corrosion rates.

The effect of no agitation was examined using a vessel set up in the usual manner, but without a stir shaft. The effect of a 25C bath temperature over 50 hours, rather than the 50C bath temperature, was examined. The 25C bath temperature reflects conditions under which the tank contents are at ambient temperature; while the 50C bath temperature reflects the effects of both radiolytic decay heat and heat from the pumps used to agitate the tank contents. The final test for this set of experiments was a control run at optimum process conditions. In addition to ICP-MS analysis for Cs concentration, the samples in this set of tests were also analyzed for iron (Fe) and aluminum (Al), which are the major oxide components of the zeolite.

SLUDGE DISSOLUTION EXPERIMENTS

As with Cs elution, the sludge dissolution experiments were run in 500 ml Pyrex reaction vessels, with ports for thermocouples, stir shafts, and sampling, as shown in Fig. 1. An appropriate amount of sludge simulant was added to the reaction vessel, followed by an appropriate amount of 8 wt% oxalic acid. The vessel was then sealed using vacuum grease and placed in a heating mantle with a temperature controller programmed to

hold the temperature at 50C (unless otherwise noted), which is the expected temperature of the material in Tank 8D-2. A stirring shaft was placed in each vessel and the contents of the vessel were agitated throughout the test period (unless otherwise noted) to simulate the effects of pumps in Tank 8D-2. Tests were run for 50 hours (unless otherwise noted) and sampling was performed at 2, 4, 20, 28, and 50 hours of contact time (unless otherwise noted). When sampling was being performed, agitation of the material in the vessel was stopped and the material was first allowed to settle for five minutes. After five minutes, approximately 5 ml were drawn from the supernate and analyzed by ICP-MS. In some of the experiments, the supernate was also analyzed by Ion Chromatography (IC) for oxalate concentration. At the completion of most of the experiments, the solids were separated from the supernate by vacuum filtration then dried and weighed to determine the total solids dissolved during the experiment.

The determination of the optimum process conditions for sludge dissolution involved six tests. The variables in this experiment were the ratio of oxalic acid to sludge, the temperature of the acid, and the contact time.

The multiple contact experiment involved two tests. Using the optimum process conditions previously determined, sludge simulant was contacted with fresh oxalic acid three times for two hours. After each contact, a 5 ml sample of supernate was drawn from each reaction vessel and sent for analysis. Two types of tests were performed: in the first test the oxalic acid in the vessel from each contact was removed after the contact and fresh oxalic acid was added; in the second test the oxalic acid was not removed after each contact.

The effects of several additional conditions on sludge dissolution at the optimum process conditions were also evaluated. The effect of the presence of corrosion products in Tank 8D-2 was examined by adding Fe2O3 as a simulant. An amount of Fe2O3 equivalent to 2400 kg of rust at the bottom of the tank was added to the vessel.

The effect of the presence of carbon steel coupons was examined. Two steel coupons were pre-weighed and suspended inside the reaction vessel so that they were completely submerged in the oxalic acid. The pair of coupons used for this test were prepared from larger U-bend coupons from earlier WVNS corrosion tests. One of the coupons, after being measured and weighed, was left "as received" with a rusted layer on the surface. The other coupon was cleaned in an inhibited acid cleaning solution to remove the rust layer. Once cleaned the "clean" coupon was measured and weighed. When the test was complete, the coupons were removed from the vessel, rinsed in deionized water, dried at room temperature, and then re-weighed to determine weight loss and estimate corrosion rates.

The effect of no agitation was examined using a vessel set up in the usual manner, but without a stir shaft. The effect of a 25C bath temperature over 50 hours, rather than the 50C bath temperature was examined. The final test for this set of experiments was a control that was run using the optimum process conditions.

In addition to the experiments described above, at the completion of the third, fourth, and fifth experiments, a determination of the solids remaining was made. At the completion of each of these experiments, most of the supernate was drained off and collected. The remaining material was poured through a vacuum filtration apparatus and the solids were collected on a piece of filter paper of known weight. The solids were

dried at room temperature for 24 hours and then weighed. Percent solids dissolved during the experiment could then be calculated using the total weight of simulant used in the experiment and an initial weight percent of 21.24% solids, which includes solids that were dissolved in the supernate as well as undissolved solids.

CESIUM ELUTION RESULTS

The experiments performed show that for Cs elution no one set of parameters tested resulted in a distinguishably higher efficiency, however, a multiple contact process appears to provide higher percentages of elution compared to a single contact. Addition of corrosion products, the presence of carbon steel coupons, and the lack of agitation all produced approximately the same level of Cs elution, which was no different from the control, after 50 hours of contact with oxalic acid. Cs elution was decreased slightly, however, when a 25C bath was used instead of the 50C bath used in most of the tests. Although the addition of Fe_2O_3 did not appear to have a significant effect on the elution of Cs, almost all of the Fe_2O_3 added to the system was dissolved. These results suggest that rust present in the tank may be extremely soluble in oxalic acid. Other tests in which carbon steel coupons were present suggest that oxalic acid may be corrosive to carbon steel since higher amounts of Fe appeared in solution than would be expected from the zeolite.

Determination of the optimum process conditions for elution of Cs from zeolite involved six tests. The variables examined were: 1) the amount of acid (20, 40, or 80 L of 8 wt% oxalic acid per kg of Cs-loaded zeolite) 2) the initial temperature of the added oxalic acid (25C or 80C) and 3) the total contact time (2, 4, 20, 28, or 50 hours).

The results of this set of tests are summarized in Fig. 2. As Fig. 2 shows, no one set of conditions consistently produced the highest elution level at each contact time. Cs elution ranged from a minimum of 52.2% (at 40 L acid/kg zeolite, 25C acid addition, 2 hour contact time) to 90.4% (at 20 L acid/kg zeolite, 80C acid addition, 50 hour contact time). In the interest of keeping plant operations simple (i.e., heating the oxalic acid to 80C would add difficulty to the process and may not significantly improve the Cs elution) and minimizing waste, 40 L acid/kg zeolite added at 25C were chosen as the optimum process conditions. The majority of the Cs elution appears to occur during the first two hours of contact, with ~60% of the Cs eluted in this time, therefore a two hour contact time was chosen as optimum for the laboratory-scale tests. A contact time this short, however, may not be feasible in full scale operations.

Fig. 2

In the multiple contact experiment Cs-loaded zeolite was contacted with fresh oxalic acid three times using the conditions of 40 L 8 wt% oxalic acid/kg zeolite, 25C acid addition, and three two-hour contact times. Two hour contacts were used because it was previously identified that >50% of the Cs was eluted after two hours contact time. Two types of tests were performed; one involving a water rinse after each contact, and one with no water rinse.

The results of the multiple contact tests show that close to 100% Cs elution was observed using two or three consecutive two hour contacts with oxalic acid. A water rinse did not appear to significantly improve or hamper Cs elution.

The effects of several additional conditions on Cs elution at the optimum process conditions of 40 L 8 wt% oxalic acid/kg zeolite added at 25C were

also evaluated. The additional conditions were: 1) addition of Fe2O3 to simulate corrosion products (rust) in the tank 2) addition of carbon steel coupons (one pre-corroded, one clean) to simulate the sides of the tank and to obtain preliminary carbon steel corrosion data 3) no agitation and 4) a 25C bath temperature instead of 50C. The supernate samples obtained from these tests were analyzed for Cs concentrations as well as concentration of Fe and Al.

After 50 hours contact time, all conditions except the 25C bath resulted in approximately the same amount of Cs eluted, an average of 90.6%, with a standard deviation of 2.5%. As would be expected, the 25C bath condition resulted in lower levels of Cs elution at longer contact times; however, the difference is within experimental error. The no-stir condition showed relatively low levels of Cs eluted at short contact times, but by 20 hours contact time, the Cs elution level had risen from 29.1% to 78.2%, and by 50 hours it was at 88.4%. Neither the addition of Fe2O3 nor the presence of carbon steel coupons appeared to have any effect on Cs elution at contact times greater than 2 hours.

The addition of Fe2O3 to simulate corrosion products in the tank did not appear to have a significant effect on the elution of Cs from zeolite or on the dissolution of Al in zeolite. It does, however, have an effect on the amount of Fe present in solution. In Fig. 3, which shows the amounts of Fe dissolved, 100% Fe dissolved means 100% of the Fe in the system. For the test in which Fe2O3 was added, this includes the Fe coming from the Fe2O3. Hence, although this test and the control both appear to have dissolved the same percentage of Fe, the total amount of Fe in solution is much higher for this test. This additional Fe may increase the number of glass logs produced by vitrification. The data indicate that 92% of the Fe in the system--including loose rust at the bottom of the tank--is in solution after 50 hours contact time.

It is interesting to note that it appears to take some time for the Fe concentration in solution to rise. At 20 hours contact time, only about 5% of the Fe in the system is in solution (corresponding to about the amount one would expect to come from the dissolution of Fe from the zeolite). By 28 hours, this amount had risen to 63%.

The presence of carbon steel coupons in the oxalic acid solution had no significant effect on either the elution of Cs from zeolite or on the dissolution of aluminum oxide (Al2O3) in zeolite. Figure 3 shows amounts of Fe greater than 100% in solution at longer contact times. In this test, 100% Fe is based on the amount of Fe in the zeolite; therefore, amounts greater than 100% would have to be attributed to Fe dissolved from the carbon steel coupons. The control test indicates that at 50 hours contact time, about 91% of the Fe from the zeolite is in solution; this suggests that amounts of Fe above the 91% in the coupon test are probably coming from the dissolution of the coupons themselves.

Fig. 3

A lack of agitation in the reaction vessel contents only appeared to affect Cs elution at short contact times. At 2 and 4 hours, 15.1% and 29.1% of the Cs was eluted, respectively, but after 20 hours, the amount of Cs eluted increased to 78.2% and by 50 hours had reached the same level as the control. Similar effects were observed in the dissolution of Fe and Al from the zeolite. These results suggest that when contact times are long (i.e., greater than 28 hours), a lack of agitation should not be detrimental to Cs elution. Cs elution, however, may be limited by

diffusion if the zeolite is in a pile and thus has less surface area exposed to the oxalic acid.

The 25C bath temperature resulted in lower levels of Cs elution at most contact times. This suggests that the temperature of the system could have an impact on the efficiency of Cs elution operations. If tank temperatures fall below the 50C used in these tests, it may be necessary to extend the duration of contact times and/or implement multiple contact treatments.

SLUDGE DISSOLUTION RESULTS

The experiments performed show that for sludge dissolution no one set of parameters tested resulted in a distinguishably higher efficiency, however, multiple contacts were not found to be advantageous. In addition, contact time did not appear to be a factor in sludge dissolution. Significant changes in the percentage of each ion dissolved were not observed after 4 hours. As with Cs elution, the addition of corrosion products, presence of carbon steel coupons, and the lack of agitation did not have a significant effect on sludge dissolution. Although the addition of Fe2O3 did not appear to have a significant effect on the dissolution of sludge, almost all of the Fe2O3 added to the system ended up in solution. These results suggest that rust present in the tank may be extremely soluble in oxalic acid. Other tests in which carbon steel coupons were present suggest that oxalic acid may be corrosive to carbon steel, since higher amounts of Fe appeared in solution than would be expected from the sludge.

Determination of the optimum process conditions for sludge simulant dissolution in 8 wt%oxalic acid consisted of six tests. The variables studied were: 1) the ratio of oxalic acid to sludge simulant (20, 40, and 80 L acid/kg sludge simulant) 2) the temperature of the acid as it was added (25C or 80C) and 3) the contact time (2, 4, 20, 28, or 50 hours). The concentration of soluble oxalate was measured by ion chromatography (IC) after each contact time in each of the six tests. Throughout the experiment, changes in the oxalate concentration were found to be less than the analytical error of 10%. These results suggest that within experimental error, no precipitation of oxalate was detected.

The concentration of each ion in solution was measured by ICP-MS after each contact time in each of the six tests. Figure 4a shows the ranges of dissolution for each ion. In Fig. 4a each dark circle represents one data point and each data point for a given ion represents a different set of conditions (i.e., L acid/kg, temperature of acid addition, contact time). The analytical error associated with each data point is 10%. For most ions, a number of data points lie within the experimental error of the maximum dissolution, making it difficult to state with any certainty that one particular set of conditions was the most effective for a given ion. However, it was possible to observe trends in the data. Upon examination of the results obtained, it becomes apparent that 20 L acid/kg sludge and 25C acid addition seem to lead to lower dissolutions, while 40 or 80 L acid/kg sludge and 80C acid addition seem, in general, to lead to higher dissolutions. Contact time did not appear to play a major role in the dissolution of most of the ions; significant changes were not observed after 4 hours contact time and, in most cases, at least 70% of the ion had dissolved after 2 hours contact time.

For most of the ions analyzed (zirconium (Zr) and cerium (Ce) being the only exceptions), maximum dissolutions were found to be over 70%. The two high data points for Ce dissolution occur at 40 L acid/kg sludge and 25C

acid addition, at 28 and 50 hours contact time. Since Ce was chosen as a surrogate for the radionuclides uranium (U) and thorium (Th), the low dissolution of Ce from the simulant is a cause for some concern. The ICP-MS measurements of the initial simulant failed to detect more than 4% of the amount added to the simulant. Therefore, it is entirely possible that these low percentages are due to the inability of the ICP-MS to detect Ce under these conditions. It is also possible that Ce simply does not dissolve, or if it does dissolve, it may form a cerium oxalate type of compound and thus not be found in solution. It is difficult to say, based on these results, whether or not Ce was a good choice for a U and Th surrogate. These results may suggest that U and Th will not dissolve well under the conditions tested or they may simply be an indication that Ce does not dissolve well under the conditions tested.

Optimum process conditions for sludge dissolution were chosen based on the results of these six tests and on the ease of use during plant operation. The optimum process conditions chosen were 40 L 8 wt% oxalic acid/kg sludge added at 25C. Forty L 8 wt% acid/kg sludge was chosen over 80 L 8 wt% acid/kg sludge in the interest of waste minimization and because 80 L acid/kg sludge was not significantly better than 40. Twenty-five degrees Celsius acid addition was chosen because 80C acid addition did not uniformly increase dissolution and in cases where it did increase dissolution, the increase was on the order of a few percent. In addition, heating the acid would present additional operational requirements in full scale operations.

In the multiple contact experiment, sludge simulant was contacted with oxalic acid three times using the conditions of 40 L 8 wt% oxalic acid/kg sludge, 25C acid addition, and a two hour contact time. Two hour contacts were chosen because the first experiment indicated that >70% of most of the ions had dissolved after two hours. Two tests were run: one in which the oxalic acid from each contact was removed from the reaction vessel before the next contact, and the other in which the fresh oxalic acid was added to the acid from previous contacts.

In the test where the oxalic acid was removed after each contact, most of the dissolution occurred during the first two hour contact. Additional contacts increased the total dissolution of ions by only a few percent. In the test where the "used" oxalic acid was left in the vessel, for many ions, after the initial contact, total dissolution appeared to decrease with subsequent contacts. The data indicate that multiple contacts with oxalic acid are not advantageous to the sludge dissolution process. The amounts of ions in solution remain constant within experimental error over the three contacts for both the case where the acid is removed after each contact and the case where fresh acid is added to that which is already present.

The effects of several additional conditions on sludge dissolution at the optimum process conditions of 40 L 8 wt% oxalic acid/kg sludge added at 25C were also evaluated. These additional conditions were: 1) addition of Fe_2O_3 to simulate the presence of corrosion products (rust) in the tank 2) addition of carbon steel coupons (one pre-corroded, one clean) to simulate the sides of the tank and to yield preliminary corrosion data 3) no agitation and 4) a 25C bath temperature instead of 50C, as stated in the initial description of the sludge dissolution experiments.

The conditions in this experiment seemed to affect the dissolution of strontium (Sr), nickel (Ni), and Fe the most. In the case of Sr, the data shows that the 25C bath decreases the Sr dissolution to well below the

control level after 50 hours contact time. Nickel dissolution is dramatically decreased by the presence of steel coupons and, to a somewhat lesser extent, the dissolution of Ni is lower than the control at 50 hours under both the no-stir and the 25C bath temperature conditions.

Fig. 4a

Fig. 4b

The addition of Fe_2O_3 to simulate corrosion products in the tank did not appear to have a significant effect on the dissolution of the ions analyzed. However, it did have an effect on the amount of Fe in solution. In Fig. 4b, 100% Fe dissolved means 100% of the Fe added to the system. For the test in which Fe_2O_3 was added, this includes Fe from Fe_2O_3. Although this test and the control both appear to have dissolved the same percentage of Fe, the total amount of Fe in the system is much higher for the test in which Fe_2O_3 was added. The data indicate that 97% of the Fe in the system, including loose rust at the bottom of the tank, is in solution at 50 hours contact time.

The data show that the presence of carbon steel coupons in the oxalic acid solution had an effect on the dissolution of both Ni and Fe in the sludge dissolution experiments, but did not have a significant effect on the dissolution of any of the other ions present in the sludge simulant. The results from the tests in which carbon steel coupons are present show that the dissolution of Ni decreases dramatically with time (from 70% after 4 hours contact to 30% after 50 hours contact) when the coupons are present. A possible explanation for this is that Ni was plated out on the surface of the coupons. Analysis of the coupon surfaces and the stripping solution might confirm whether this is the cause of the dramatic decrease in Ni in solution when carbon steel coupons are present. If this is the case, it is possible that once the oxalic acid cleans the oxide off the tank wall other metals will also be reduced and plate out on the tank surfaces. These other metals might include radionuclides, which would not be a desirable situation.

Figure 4b shows that amounts of Fe greater than 100% are in solution at all contact times except 4 hours. In this test, 100% Fe is based on the amount of Fe in the sludge simulant alone; therefore, amounts greater than 100% would have to be attributed to Fe dissolved from the carbon steel coupons. The control test indicates that at 50 hours, approximately 96 wt% of the Fe from the simulant is in solution. This suggests that amounts of Fe above 96% 10% in the coupon tests are probably due to the dissolution of the coupons themselves.

A lack of agitation of the reaction vessel contents did not appear to have a significant effect on the dissolution of any of the ions analyzed in these tests except for Ni, which exhibited slightly lower dissolution than the control at longer contact times. A 25C bath temperature appeared to affect the dissolution of both Sr and Ni. Both of these ions exhibit somewhat lower dissolution than the control in a 25C bath.

The solids remaining at the end of most of the experiments were collected and weighed to determine the amount of solids that had been dissolved by treatment. An average of 74% (with a standard deviation of 2.6%) of the solids were dissolved in the tests where the determination was made. The remaining solid material from one of the tests was analyzed by X-ray diffraction. The material was found to be a complex mixture of phases. The main phases identified are listed in Table I along with a semi-quantitative wt %. Additional phases are likely to be present, but were

not identifiable, and the semi-quantitative analysis ignores the presence of additional unidentified phases. The presence of SiO_2 (quartz) and ZrO_2 (Baddeleyite) is not surprising since these are both difficult compounds to dissolve. Also, the large percentage of $C_6H_{20}Ce_2O_{22}$ (cerium oxalate hydroxide) present agrees with the ICP-MS analysis for Ce in the supernatant, which indicated that very little of the Ce initially present in the sludge had been dissolved.

Table I

CONCLUSIONS

The original objectives of Cs elution and sludge dissolution for which the experiments discussed above were conducted included maximizing Cs elution and sludge dissolution, and investigating the effect of tank corrosion products. In addition to these objectives, the test condition of oxalic acid wt % was set at 8 wt%. After reviewing the results obtained, however, a modified set of objectives was identified that added minimizing the dissolution of iron, minimizing tank corrosion, and providing a feed compatible with the current vitrification waste form specification to the objectives already defined. With this new set of objectives, additional Cs elution tests that used 4 and 1 wt% oxalic acid solutions and corrosion tests were performed.

The following conclusions are based on results of work presented in this report as well as some of the follow-up testing indicated above:

The data show that lower percentages of Cs may be eluted when the wt% of oxalic acid is lowered (i.e., from 8 wt% to 4 or 1 wt%). Using 8 wt% oxalic acid, as described above, a maximum of 99.9% Cs was eluted with an oxalic acid-to-zeolite ratio of 40 L/kg, a temperature of 25C, and three 2-hour contacts. Approximately 60-70 % Cs was eluted, however, using 4 and 1 wt% oxalic acid. (Note: A higher oxalic acid-to-zeolite ratio was used for the 4 and 1 wt% tests.)

The data show that by using 8 wt% oxalic acid, an oxalic acid-to-sludge ratio of 40 L/kg, an acid temperature of 25C, and a single contact, 70-75 wt% of the solids present in the sludge can be dissolved. The dissolution of the radionuclides may be considerably lower, <10%, based on the dissolution of Ce that was used as a surrogate for U and Th.

The data show that larger amounts of Fe_2O_3, which represents corrosion products present in the tank, are solubilized when 8 wt% oxalic acid solutions are used. By using 8 wt% oxalic acid with the conditions specified in the first bullet, ~ 90% of the Fe_2O_3 was solubilized compared to ~ 15-20 % solubilized for 4 and 1 wt%. (Note: A higher oxalic acid-to-zeolite ratio was used for the 4 and 1 wt% tests.)

Oxalic acid corrosive tests were performed using A516 Grade 55 mild steel test specimens, which has essentially the same chemical composition and microstructure as the type of steel used in fabricating the tanks.*** These tests showed that even at relatively modest temperatures (50C) and short exposures to 4 and 8 wt% oxalic acid solutions (1 to 3 weeks), the corrosion rate is quite high. The corrosion appeared as localized pitting and crevice corrosion for submerged test specimens; however, vapor space corrosion was negligible at the conditions tested.

The experiments performed and the results obtained have provided a basis for declaring that oxalic acid can elute Cs from zeolite and dissolve sludge. Questions and issues still exist, however, that need to be resolved before oxalic acid can be identified as being feasible to clean carbon steel HLW tanks. Some of the questions and issues, which were briefly mentioned in the conclusions stated above, are:

Iron present at too high a level is detrimental to vitrification. How can the amount of iron dissolved be minimized?

The goal in maximizing sludge dissolution relates to mobilizing the radionuclides present enabling them to be transferred to vitrification. If Ce is an accurate surrogate for U and Th, what impact will precipitated U and Th oxalate compounds have on this goal i.e., can they still be mobilized and transferred?

As stated above, the data show that oxalic acid is corrosive to the mild steel test specimens. For purposes of safety, how can corrosion to the tanks be minimized?

In support of the WVDP's effort to evaluate options to meet stabilization objectives for the HLW tanks on site, the investigation of the feasibility of using oxalic acid will continue. The basis of information obtained to date will be reviewed and used to determine the path forward that will enable the determination of feasibility to be made.

DISPOSITION OF PUREX CONTAMINATED NITRIC ACID THE ROLE OF STAKEHOLDER INVOLVEMENT

W. G. Jasen
R. A. Duncan
Westinghouse Hanford Company
Richland, Washington 99352

ABSTRACT

What does the United States space shuttle and the Hanford PUREX facility's contaminated nitric acid have in common. Both are reusable. The PUREX Transition Project has achieved success and minimized project expenses and waste generation by looking at excess chemicals not as waste but as reusable substitutes for commercially available raw materials. This philosophy has helped PUREX personnel to reuse or recycle more than 2.5 million pounds of excess chemicals, a portion of which is the slightly contaminated nitric acid. After extensive public review, the first shipment of contaminated acid was made in May 1995. Removal of the acid was completed on November 6, 1995 when the fiftieth shipment left the Hanford site. This activity, which avoided dispositioning the contaminated acid as a waste, generated significantly more public input and concern than was expected. One of the lessons learned from this process is to not underestimate public perceptions regarding the reuse of contaminated materials.

The quantity of radioactivity in the contaminated acid (each individual shipment) met the criteria for a low specific activity shipment under the Department of Transportation regulations. In the total volume of acid there was less than 0.3 grams (0.01 ounces) of plutonium and 7,400 kilograms (16,300 pounds) of uranium, of which approximately 72 kilograms (158 pounds) was U-235 (i.e. fissile material). Low specific activity shipments are routinely shipped across the country. The handling (including transportation) of hazardous liquid chemicals occurs daily in the continental United States. In 1993 alone, approximately 5.3 X 109 liters (1.4 billion gallons) of nitric acid was produced and transported internationally; without substantial incident. However, the transport and disposition of the PUREX contaminated acid generated more interest and comments than was expected for an activity of this type. In comparison, spent fuel shipments from PUREX generated little interest from reviewers.

PUREX DEACTIVATION

In December 1992, DOE directed that the PUREX Plant be shut down and deactivated because it was no longer needed to support the nation's weapons-grade plutonium production. The scope of the deactivation project involves many activities necessary to place the PUREX Plant in an environmentally safe and stable state for long-term surveillance and maintenance. Removing major hazards from the PUREX Plant, such as excess chemicals, spent fuel, and residual plutonium are major goals of the deactivation project. This will reduce the risk of exposure to both onsite workers and members of the general public. Stakeholder involvement has played a major role in the formation of deactivation plans, implementation of selected strategies and accomplishment of specific goals.

BACKGROUND INFORMATION

Historically, nitric acid was used at the Hanford Site's PUREX Plant to dissolve irradiated fuel elements, and for the separation and purification of uranium, plutonium, and neptunium in solvent extraction operations. The nitric acid was recovered and reused during processing. A specific result of cessation of PUREX Plant operations is that excess chemicals are available, including approximately 692,000 liters (183,000 gallons) of slightly radioactively contaminatednitric acid.

DEACTIVATION PLANNING

The original project baseline for disposition of the excess 10 molar nitric acid was to sugar denitrate the material to approximately 1 molar acid in the PUREX canyon. This process would generate between 300 to 400 metric tons of nitrogen oxides or NOx as gaseous effluent. Denitration would reduce the liquid volume to be transferred for disposal to tank farms by about 33 percent. This action eliminates the acid but provides no beneficial use for the material, while having potential present and future environmental impacts.

Westinghouse sought ways to beneficially use the material to avoid processing the acid as waste. Brainstorming sessions were held to seek innovative ways to use the material. With no use for the surplus acid identified within the DOE complex, private sector interest was solicited. An expression of interest was received from British Nuclear Fuels private limited company (BNF plc), the sole respondent to the Commerce Business Daily advertisement.

Abandoning the treatment option to sugar denitrate the acid and pursuing the beneficial reuse of the material, along with other changes to the project, resulted in saving $37 million and shortened the duration of the Deactivation project by 10 months. Beneficial reuse of the acid is the most economical and cost effective solution for disposition of the acid.

DOCUMENTATION

The concept of shipping the acid to England for use in a process similar to PUREX was previously addressed under the National Environmental Policy Act (NEPA) as a Categorical Exclusion or (CX). Nuclear proliferation became a potential concern with interest groups. Later DOE determined that the action would meet conditions of the regulations that require additional NEPA review. Therefore an Environmental Assessment was prepared to provide a quantitative analysis of potential risks and environmental impacts associated with the proposed action and alternatives, in the continental U.S. and on international waters, and to allow a determination of whether or not an Environmental Impact Statement is required.

Preparation, review, and approval of the Environmental Assessment took many months. An Ad Hoc stakeholder committee, consisting of representatives from three local interest groups, DOE, and Westinghouse, was formed to facilitate document preparation and review. The Ad Hoc stakeholder committee was used to improve the nitric acid Environmental Assessment and address many different opinions prior to issuing the document for comment. Subsequently, the draft document was sent to more than 200 individuals, states, Indian Nations, interest groups and affected public for public comment. Public meetings were held on the east coast at the three proposed shipping ports; Portsmouth, Virginia, Baltimore, Maryland and Newark, New Jersey. Figures 1 and 2 show the posters used at the public meetings. During the public comment period more than 50 inquiries for information, clarification, or comment were made. All comments were addressed in the final Environment Assessment. Comments included a wide range of topics and issues. Some comments were specific to the activity and some comments were unrelated to the project. Comments ranged from concerns about potential spread of contamination to proliferation issues. Comments on proliferation were addressed in the "Environmental Assessment, Disposition and Transportation of Surplus Radioactive Low Specific Activity Acid, Hanford Site, Richland, Washington," DOE/EA-1005, as follows:

In evaluating the nonproliferation policy aspects of the proposed shipment, DOE considered the facts that BNF plc has a readily available supply of nitric acid, which could be procured from any number of U.S. or other commercial sources, and that interested parties such as Ecology, U.S.Environmental Protection Agency (Region 10), Yakima Indian Nation, and the Confederated Tribes of the Umatilla Indian Reservation do not object to the shipments. In addition, the proposed shipment appeared to be a case-specific solution to a material disposition problem, promoting waste minimization and reducing potential emissions to the environment. The export would not make a material contribution to the proliferation of weapons of mass destruction and would be consistent with Executive Order 12114, Environmental Effects Abroad of Major Federal Actions. These facts appeared to support the position that the transfer of nitric acid from the PUREX Plant was a policy-neutral decision, and did not set a precedent from either a technical or policy standpoint.

Many comments were associated with the transport of the acid across the United States. Some states requested advance notice of shipments. The Department of Energy instituted weekly conference calls to keep states and other interested individuals informed on the status of the shipments. A Finding of No Significant Impact or (FONSI) was approved by the Hanford Site Manager in May 1995. Shortly there after the first nitric acid shipments to England were made. Figure 3 shows PUREX employees loading acid into the shipping container. The last shipment left the Hanford site on November 6, 1996. A total of 707,000 liters (187,000 gallons) of acid were shipped.

LESSONS LEARNED

The PUREX Transition Project team developed a good working relationship with state/federal regulators/stakeholders. Early and frequent contact with interest groups is key to project success. Flexibility is also key to success. Working directly with outside groups such as the Ad Hoc committee helped to produce an initial draft of the environmental assessment that was more palatable to the public. However, it is ironic that due to specific concerns, public comment on the disposition of the

slightly contaminated acid generated significantly more interest than the transfer of spent fuel. The lesson here is one of perceptions. In this case the greater risk was not the biggest concern. When addressing unique situations such as the disposition of PUREX contaminated acid, it is essential that "normal procedures" not be totally relied upon. Due to frequent interaction with the regulators and stakeholders deactivation project goals were accomplished without delay to field work.

POSITION FOR DETERMINING GAS PHASE VOLATILE ORGANIC COMPOUND CONCENTRATIONS IN TRANSURANIC WASTE CONTAINERS

M.J. Connolly
K.J. Liekhus
Lockheed Idaho Technologies Company
Idaho National Engineering Laboratory
Idaho Falls, Idaho 83415

S.M. Djordjevic
C. A. Loehr
L.R. Spangler
Benchmark Environmental Corporation
Albuquerque, New Mexico 87110

ABSTRACT
In the conditional no-migration determination (NMD) for the test phase of the Waste Isolation Pilot Plant (WIPP), the U.S. Environmental Protection Agency (EPA) imposed certain conditions on the U.S.Department of Energy (DOE) regarding gas phase volatile organic compound (VOC) concentrations in the void space of transuranic (TRU) waste containers. Specifically, the EPA required the DOE to ensure that each waste container has no layer of confinement that contains flammable mixtures of gases or mixtures of gases that could become flammable when mixed with air. The EPA also required that sampling of the headspace of waste containers outside inner layers of confinement be representative of the entire void space of the container. The EPA stated that all layers of confinement in a container would have to be sampled until DOE can demonstrate to the EPA that sampling of all layers is either unnecessary or can be safely reduced. A test program was conducted at the Idaho National Engineering Laboratory (INEL) to demonstrate that the gas phase VOC concentration in the void space of each layer of confinement in vented drums can be estimated from measured drum headspace using a theoretical transport model and that sampling of each layer of confinement is unnecessary. This report summarizes the studies performed in the INEL test program and extends them for the purpose of developing a methodology for determining gas phase VOC concentrations in both vented and unvented TRU waste containers. The methodology specifies conditions under which waste drum headspace gases can be said to be representative of drum gases as a whole and describes a method for predicting drum concentrations in situations

where the headspace concentration is not representative. The methodology addresses the approach for determining the drum VOC gas content for two purposes: operational period drum handling and operational period no-migration calculations.

INTRODUCTION

Characterization of transuranic (TRU) wastes destined for the Waste Isolation Pilot Plant (WIPP) will include sampling of gases in the headspaces of waste drums for volatile organic compounds (VOC). The headspace gas VOC concentrations will be used to determine potential flammability of gases and VOC concentrations in drums for transportation and Resource Conservation and Recovery Act (RCRA) compliance purposes (DOE 1995). in the conditional no-migration determination (NMD) for the test phase of the WIPP facility (55 FR 47700), the Environmental Protection Agency (EPA) required that the U.S. Department of Energy (DOE) must ensure that each waste container emplaced underground at the WIPP has no layer of confinement that contains flammable mixtures of gases or mixtures of gases that could become flammable when mixed with air. For purposes of a no-migration demonstration, DOE must also characterize the nonflammable volatile hazardous constituents in TRU waste containers. The EPA stated that all layers of confinement in a container would have to be sampled until DOE can demonstrate to the EPA, based on the data collected, that sampling of all layers is either unnecessary or can be safely reduced. This position paper summarizes a methodology that has been proposed in Connolly et al. (1995) that addresses these conditions and alleviates the requirement of sampling all layers of confinement.

A test program was conducted at the Idaho National Engineering Laboratory (INEL) to demonstrate that the VOC concentration in the void space of each layer of confinement in vented drums can be estimated using measured drum headspace and a model incorporating theoretical diffusion and permeation transport principles and that sampling of each layer of confinement is unnecessary. The model and model validation results provide information that are used to address the headspace VOC concentration representativeness issue raised by the EPA for vented containers.

This report presents the methodology for determining VOC concentrations in both vented and unvented drums for existing waste packaging configurations. The methodology specifies conditions under which drum headspace gases can be said to be representative of drum gases as a whole and describes a method for predicting drum concentrations in situations where the headspace concentration is not representative. For the purpose of predictions of gas phase VOC concentrations, innermost layers of confinement are the polymer bag layers closest to the waste; rigid inner layers of confinement, such as polymer bottles, are not included. The methodology presented in this paper addresses the approach for determining the drum VOC gas content for two purposes: operational period drum handling and operational period no-migration calculations.

VOC TRANSPORT STUDIES

The INEL test program was developed to predict innermost bag gas phase VOC concentrations from the headspace gas VOC concentrations using VOC transport models and data obtained from waste drum sampling. This program consisted of three stages.

In the first stage of the test program, a transient VOC transport model was developed to estimate the VOC concentration within laboratory-scale waste drums as a function of time (Liekhus et al. 1994a). The testing

demonstrated that transient gas phase VOC concentrations can be predicted based on theoretical transport mechanisms. Model equations accounted for three primary mechanisms for VOC transport from a void volume. These mechanisms were VOC permeation across a polymer confinement layer, VOC diffusion across an opening in a layer of confinement, and VOC solubility in a polymer confinement layer.

In the second stage of the INEL program, a steady-state transport model was developed to predict concentrations in laboratory-scale vented waste drums containing simulated waste sludge based on knowledge of drum headspace VOC concentration and waste drum configuration (Liekhus et al. 1994b). Experiments were performed to measure the VOC concentration in laboratory-scale vented waste drums containing two types of simulated waste sludge with differing compositions (Liekhus et al. 1994b). Experimental results were expressed as a ratio between drum headspace VOC concentration and the VOC concentration inside the innermost polyethylene bag. Model equations were used to determine the effect of model parameters on the estimated concentration difference across a transport boundary, such as the rigid drum liner or polymer bag, using permeation as the transport mechanism.

In the third stage of the INEL experimental program, the model developed in the second stage was used to estimate VOC concentrations in 64 actual waste drums from INEL and the Rocky Flats Environmental Technology Site (Rocky Flats). The effectiveness of the model in estimating VOC concentration was examined for vented waste drums containing different waste types and packaging configurations. The model results demonstrated that maximum VOC concentrations within actual waste drums can be estimated from drum headspace gas sampling data. Details of the gas sampling and analysis, equipment used, procedures employed and quality control procedures are provided in Liekhus (1995).

The VOC transport model was said to be unbiased if the 95-percent confidence limits on the mean logarithm of the ratio of the VOC concentration in the innermost layer of confinement to the maximum VOC concentration in the headspace is zero. Otherwise, the model is said to have a positive or negative bias. Transport model predictions were unbiased or positively biased (i.e., over estimated) for the maximum measured concentrations of 11VOCs within vented waste drums. These VOCs are carbon tetrachloride, chloroform, 1,1-dichloroethane, 1,1-dichloroethylene, methanol, methylene chloride, tetrachloroethylene, 1,1,1-trichloroethane, trichloroethylene, 1,1,2-trichloro-1,2,2-trifluoroethane, and toluene. The model exhibited a negative bias for 2 VOCs (p-xylene and acetone). The model was unbiased in estimating the total VOC concentration within the innermost layer of confinement for waste drums containing a maximum of four layers of polymer bags that were all sampled within one day and exhibiting detectable concentrations in inner bags. The model exhibited a positive bias in estimating the total VOC concentration within the innermost layer of confinement of waste drums containing a maximum of two or five layers of polymer bags.

Model precision was characterized for 13 VOCs and three drum configurations by the lower 90/90 tolerance limit (LTL) for the logarithm of the ratio described earlier. Based on the tolerance limits, the VOC transport model predicts an innermost bag VOC concentration that, with 90-percent confidence, will not be less than 50 percent of the maximum measured VOC concentration in at least 90 percent of the waste drums for 8 VOCs and two of the waste drum configurations. These VOCs are acetone,

1,1-dichloroethane, 1,1-dichloroethylene, methylene chloride, toluene, 1,1,1-trichloroethane, trichloroethylene, and 1,1,2-trichloro-1,2,2-trifluoroethane. The VOC transport model predicts that the VOC concentration will not be less than 33 percent of the maximum measured VOC concentration in at least 90 percent of the waste drums for 3 VOCs and waste drums with a maximum of four layers of polymer bags. The three VOCs are chloroform, tetrachloroethylene, and p-xylene. For carbon tetrachloride and methanol, model estimates will not be less than 20 percent of the maximum measured VOC concentration in at least 90 percent of the waste drums.

DRUM AGE CRITERION FOR HEADSPACE GAS SAMPLING

There is a certain age criterion that must be met by a drum of TRU waste in order for headspace gas samples to be either representative of gases in the drum or appropriate to use in predicting innermost bag VOC gas phase concentration. The drum age criterion (DAC) defines the age of a drum necessary to reach 90-percent of steady-state concentration within all of the bags and the rigid drum liner. The DAC establishes the time after waste packaging necessary to wait prior to drum headspace sampling to help ensure that the headspace sample analyses are suitable for their intended use.

DACs for two packaging configurations have been determined using transient VOC transport models and indicator VOCs selected on the basis of health risks and magnitude of concentration. The DACs are given in Table I. For drums of Waste Types I and IV, the DAC is 225 days. For drums of Waste Types II and III, the DAC is 142 days.

Table I

Indicator VOCs were selected by using two separate screening techniques and having the screened VOCs comprise the set of indicator VOCs. The screening techniques are consistent with the purposes for determining gas phase VOC concentrations in drums; one of the screening techniques focused on flammability issues related to operational period drum handling and the second focused on human health risk from inhalation for the operational period. To screen for operational period drum handling, the magnitude of VOC concentration in headspace gas samples from 465 INEL and Rocky Flats drums was examined.

The screening resulted in 11 distinct indicator VOCs. For drum handling, n-butanol, methyl ethyl ketone, methyl isobutyl ketone, and methanol were screened for inclusion in the indicator set. For operational period human health risk, 1,1-dichloroethylene, carbon tetrachloride, chlorobenzene, chloroform, methylene chloride, methyl ethyl ketone, 1,1,2,2-tetrachloroethane, trichloroethylene, and toluene were screened and included as indicator VOCs.A computer program was used to calculate the required drum age or vent time for each indicator VOC for three drum categories and two drum packaging configurations. The three drum categories are:

Drum Category 1, Existing Vented Drums: The existing vented drums are those that were stored as unvented drums and subsequently vented, the rigid drum liners punctured, and stored again for a period of time. Drums in this category must have been unvented for a sufficient time such that equilibrium concentrations existed within all confinement layers at the time of venting.

Drum Category 2, Newly Packaged Vented Drums: The newly packaged vented drums consist of drums and associated rigid drum liners that were vented

at the time of packaging. In this category, steady-state concentrations do not exist within all confinement layers at the time of packaging.

Drum Category 3, Existing Unvented Drums: The existing unvented drums are those drums that have been stored as unvented drums for a period of time. The drums are to be vented (i.e., the drum liners punctured and carbon composite filters installed in the drum lids) and headspace gas samples taken from inside the rigid drum liners at the time of venting. Two packaging drum configurations were considered in determining the DACs from the calculated drum ages and vent times. For drums containing sludges (Waste Types I and IV), there are two large bags within the rigid drum liner providing two inner layers of confinement. For solid waste (Waste Types II and III), it is conservatively assumed that five layers are within the rigid drum liner. The drum filter type is assumed to be NFT-020 for both packaging configurations; this assumption is considered conservative since NFT-020 filters are the most restrictive regarding the release of compounds of filter types being used in the DOE complex (Liekhus 1995). The longer of the following, for each configuration and over all indicator VOCs, are taken as the DACs:

Calculated vent time for newly packaged vented drums and

The sum of calculated vent time for existing vented drums and calculated drum age for existing unvented drums

The DACs that result are given in Table I. Potential future packaging configurations (e.g., those using filtered bags) were not considered and will require additional analyses to determine the appropriate DAC.

DISCUSSION OF TRANSPORT MODELING

The INEL test program and its associated transport modeling demonstrates that VOC transport can be modeled based on mathematical simulation of diffusion and permeation processes. This demonstration took place in three stages: transient VOC transport from vented laboratory-scale drums, steady-state VOC transport in laboratory-scale vented waste drums containing simulated waste sludge and the application of the steady-state model to actual waste drums. Based on comparing model results to actual waste drum concentrations, the steady-state VOC transport model demonstrated that innermost bag gas phase VOC concentrations can be predicted from headspace gas concentration data. Because these predictions can be made, sampling and analysis of inner layers of confinement will not be necessary.

The predictions can be made using prediction factors that conservatively approximate the steady-state model predictions. The prediction factors are derived by solving the steady-state model in terms of the ratio between the innermost layer gas phase VOC concentration and the headspace gas VOC concentration. The prediction factors have been computed for 29 VOCs for the two packaging configurations used for the DACs. Use of the prediction factors will be conservative for cases where the actual package has fewer layers than that assumed for the prediction factor. The prediction factors are also based on conservative assumptions of filter diffusivities. The prediction factors are given in Table II and range from 1.1 to 9.5 for Waste Types I and IV and from 1.7 to 39 for Waste Types II and III. To predict the innermost bag gas phase VOC concentration, the headspace gas VOC concentration and associated prediction factor should be multiplied.

Table II

The steady-state VOC transport model and the prediction factors are valid when the DAC has been met. The DAC establishes the time after waste

packaging necessary to wait prior to drum headspace gas sampling to be able to accurately predict the innermost layer gas phase VOC concentration within a drum. The innermost layer gas phase VOC concentration prediction will be the maximum predicted value. The DAC also establishes the waiting time that will ensure that the transport rates between layers of confinement are equal and headspace concentrations can be used in calculations for emissions through the drum filter.

If the drum is unvented (Drum Category 3) and the DAC has been met, modeling shows that the headspace gas within the rigid liner is representative of the drum gases within all layers of polymer confinement, because equilibrium has been reached. If the drum is vented (Drum Categories 1 and 2) and the DAC has been met, the innermost gas concentration can be predicted from the headspace gas concentration using the prediction factors in Table II. The predicted innermost bag concentration is concluded to conservatively represent the maximum concentration within a drum. In addition, if the DAC has been met, the headspace concentration for Drum Categories 1 and 2 can be said to represent headspace concentrations that control the rate of emissions through the drum filter over time.

PROPOSED APPROACH

The proposed approach provides prescriptions for determining drum gas phase VOC concentrations for operational period drum handling and operational period no-migration calculations for each of the three drum categories. The prescriptions are based on the DAC being met prior to headspace sampling and involve methodologies outlined below. Either headspace gas measurements or predictions of innermost bag concentrations, as appropriate, will be used.

Operational Period Drum Handling

Gas phase VOC concentrations in drums will be determined for the purpose of assessing flammability. The maximum gas phase VOC concentration is the concentration of interest for this assessment. The approach is to use predicted concentrations for the maximum in cases where the headspace concentration is not representative of the maximum. The basic steps to the approach are as follows:

1. Determine the drum packaging configuration.
2. Establish and meet the DAC.
3. Sample and analyze headspace gas.
4. Determine Drum Category. Determine drum concentrations as follows:

a. For existing vented drums (Drum Category 1), determine the predicted value using the factors in Table II. The predicted value will be used for the drum concentration.

b. For newly packaged vented drums (Drum Category 2), the predicted value will be used as for existing vented drums (see a.).

c. For existing unvented drums (Drum Category 3), headspace concentrations within the rigid drum liner will be used, because the DAC ensures representativeness.

The selected flammable VOCs concentration values will be summed for each drum.

Operational Period No-Migration Calculations

Gas phase VOC concentrations in drums will be determined for the purpose of calculating VOC emissions through drum filters. Because steady-state conditions are required, the VOC emission rate from a vented drum is a function of the drum headspace VOC concentration and the VOC diffusion

characteristic across the drum filter. VOC concentrations in inner layers of confinement are not used, and thus are not selected for the drum concentration; rather, the approach is to use headspace concentrations. The basic steps to the approach are as follows:

1. Determine the drum packaging configuration.
2. Establish and meet the DAC.
3. Sample and analyze headspace gas.
4. Determine Drum Category. Determine drum concentrations as follows:

a. For existing vented drums (Drum Category 1), the headspace concentration will be used.

b. For newly packaged vented drums (Drum Category 2), the headspace concentration will be used as for existing vented drums.

c. For existing unvented drums (Drum Category 3), headspace concentrations within the rigid drum liner will be used.

ABSTRACT

This paper addresses: 1) the selection of borosilicate glass as the reference waste matrix for solidifying high-level radioactive wastes at the Savannah River and West Valley Sites using the vitrification process; 2) controlling the composition of the feed at the melter to ensure

achieving a quality glass product and meeting processing constraints, and 3) the historical development of glass-former compositions at DWPF.

Most countries throughout the world, including the United States, that have produced HLW from the reprocessing of nuclear fuel have selected or are evaluating borosilicate glass as a final waste form. The principal reasons for the international focus on the production of waste glass, particularly on borosilicate waste glasses, are the ease of processing and the relative insensitivity of glass properties to fluctuations in waste composition. The chemical durability of borosilicate glass has also been an important consideration in its choice as a HLW form.

Borosilicate waste glass incorporates the constituents of the high-level waste, which includes Cs-137, Pu-238, and Sr-90, directly into its molecular structure. It can accommodate many different elements and wide variations in waste composition. However, the composition of the melter feed has to be controlled to achieve a satisfactory product and to meet processing constraints. The selection of the glass forming (frit) composition for a given waste composition is made based on desired waste loading, the composition of the high-level radioactive waste, and processing considerations. The goal of tailoring this glass composition is to obtain the optimum balance of all the important glass properties including viscosity of the glass melt, glass liquidus temperature, and glass durability.

Following a "system approach", the Savannah River Site (SRS) developed glass-former compositions that balances glass durability against process reliability. The primary processing properties are the viscosity and waste solubility. In the approach taken by SRS , an optimum frit is defined as one which maximizes waste solubility (by minimizing liquidus temperature) and which yields waste glasses which leach as little material as possible in the standard leach test and which are in the proper range of viscosities.

BOROSILICATE GLASS SELECTION AS FINAL WASTE FORM

Glass has been recognized by a number of countries as a promising medium for the immobilization of high-level radioactive waste (HLW) because of the commonly perceived durability of silicate glasses and the capacity of the glass to incorporate many different elements -- a necessity for radioactive waste immobilization. The projected high glass durability over long periods of time is indicated by the survival of naturally occurring glasses for millions of years and synthetic glasses for thousands of years. The technology of glass fabrication also has a long history. Glass has been made and used since ancient times, and borosilicate glasses have been made and used since the early 1900s (1).

In 1978, an independent panel organized by the American Physical Society (2) concluded that an emplacement of vitrified waste into a geologic repository was likely to provide an adequate solution to the problem of HLW management. Subsequently, DOE's National High Level Technology Program conducted a review of all options for immobilization of HLW along with assessments of the technology required at the various sites (3). Research was conducted on 17 candidate waste forms by national laboratories, universities, industrial laboratories, and DOE facilities. An independent review of this research, conducted by the Alternative Waste Form Peer Review Panel (4), reduced the list of waste form candidates form 15 to 8. Finally, the Panel ranked these 8 candidate waste forms on the basis of a weighted evaluation using leach resistance, waste loading, mechanical strength, radiation stability, and thermal

stability as criteria, with leach resistance from static leach tests receiving the highest weighting factor. In the final ratings, borosilicate glass was ranked first.

INTERNATIONAL FOCUS ON BOROSILICATE WASTE GLASSES

The first production facility to convert HLW into borosilicate glass using the vitrification process was the AVM facility in Marcoule, France in 1978. This facility continues to run today. Currently, the world's most mature vitrification technologies are the French process, which uses a rotary calciner and metallic melter, and several adaptations of the liquid- or slurry-fed ceramic lined melter (LFCM). The French process has been adopted in the Windscale Vitrification Plant facility at Sellafield in Great Britain. Three countries have committed to development of the LFCM technology: Germany, the U.S. and Japan. In 1979, the PAMELA Plant began initial vitrification operation at Mol, Belgium, and went radioactive in 1986. In the U.S., the Savannah River Site Defense Waste Processing Facility (DWPF) and the West Valley Demonstration Project (WVDP) will begin radioactive operation in 1996. Japan's Tokai Vitrification Facility (TVF) will begin operations in 1998. A pilot "hot" facility is operating now. All these processes produce borosilicate glass as a final waste form.

Best Demonstrated Available Technology

In 1990, vitrification of HLW was designated by the U.S. Environmental Protection Agency (EPA) as the Best Demonstrated Available Technology (BDAT) (5) for high-level waste. The Agency provided notice in the proposed rule (54 FR 48492) that DOE was providing, to the Agency, vitrification treatment data and that these data were available during the comment period for notice and public comment. The Agency concluded, after analyzing the data, reviewing comments, and performing a site visit, that vitrification will provide effective immobilization of the inorganic constituents in high-level waste.

GLASS PROCESS AND PRODUCT PROPERTIES

Vitrification of Waste

Vitrification of high-level radioactive waste at the SRS* will be accomplished in slurry-fed joule-heated, ceramic-lined melters. These melters will be fed and poured continuously. A full DWPF melter will hold enough glass to fill 4-5 canisters or about 7500 kg of glass. The average residence time of the molten glass in the DWPF melter will be 65 hours. The glass batch will be melted by Joule heating using two pairs of flat, parallel, Inconel electrodes immersed in the melt. The glass will be poured by a vacuum process. An advantage of a ceramic-lined melter is that ceramic refractories are more temperature and corrosion resistant than typical metal liners thus yielding higher melter life cycle. Development of the slurry feeding concept was an important development for the vitrification of nuclear waste. Slurry feeding significantly reduces capital costs and greatly simplifies the operation by eliminating the need to either dry or calcine the slurry prior to vitrification. Slurry feeding eliminates the capital cost of calcining and yields a more homogeneous feed.

Waste Acceptance Product Specifications

From a production perspective, the main determinant of a satisfactory borosilicate waste glass form is satisfying the requirements of the DOE Office of Environmental Management's (EM) Waste Acceptance Product Specifications for Vitrified High-Level Waste Forms (WAPS) (6). These specifications define the criteria that the waste glass products must

satisfy before they will be accepted by the U.S. DOE Office of Civilian Radioactive Waste Management (OCRWM) for disposal. The WAPS are divided into five sections, dealing with the waste form (borosilicate glass), the canister, the canistered waste form, quality assurance, and documentation. The underlying rationale for most of the specifications of the EM WAPS can be traced to the DOE Office of Civilian Radioactive Waste Management's Waste Acceptance System Requirements Document (WA-SRD) (7). The waste form is specified to be borosilicate waste glass. The chemical composition, crystalline phase projections, radionuclide inventory, a Product Consistency Test result or projection, and other characteristics must be reported for the glass. The canister must be fabricated from austenitic stainless steel to specific dimensions and be identifiable. The canistered waste form must be sealed closed, be free of foreign materials, meet heat generation and dose limits, be capable of surviving a specific drop test, and meet other requirements.

Melter Feed Composition Effects

Just as the expression "high-level waste" does not refer to one waste composition, the expression "borosilicate glass" does not refer to one glass composition, but instead to the family of compositions whose primary glass-forming ingredients are boron and silicon. Borosilicate waste glass is a vitreous material which incorporates the constituents of the high-level waste directly into its molecular structure. It can accommodate many different elements and wide variations in waste composition. However, the composition of the melter feed has to be controlled to achieve an acceptable product and to meet processing constraints.

The chemical composition of the melter feed is the primary determinant of the chemical durability of the waste glass product and many of the important melt processing properties (e.g., viscosity). Thus, chemical composition of the melter feed is the most important variable to be controlled. Since an incorrectly formulated glass cannot easily be remediated once it has been poured into a canister, the feed composition must be correct. The selection of the frit composition for a given waste composition is based on the desired waste loading, the compositions of the high-level radioactive waste, and processing considerations.

The compositions of nuclear waste glasses vary based on the particular balance of physical, chemical, and thermal properties which is desired, the types of equipment being used for processing, and the types of waste being processed. The viscosity of the glass melt must fall within a carefully defined range to assure that the glass will melt properly, will be properly homogenized via viscous flow within the melter, and will pour from the melter. If the viscosity is too low, excessive attack on the refractories in the melter will result. The temperature at which crystals begin to form in the glass if the temperature is maintained below a minimum temperature, termed the glass liquidus temperature, is also determined by the glass composition. Components that tend to make the glass more durable also tend to raise its viscosity and its liquidus temperature. Higher viscosities make processing more difficult while higher melting temperatures required to overcome high liquidus temperatures and lower viscosities can result in increased volatilization. The goal of tailoring the glass composition is to obtain the optimum balance of all the important glass properties.

High-level radioactive waste is added at selected waste loadings to borosilicate glass frit or to components which when melted together will

form the desired borosilicate glass matrix. The primary ingredients of the borosilicate glass frit are silicon dioxide (SiO_2), boron oxide (B_2O_3), and alkali metal oxides (Na_2O, K_2O, and Li_2O). Other ingredients are added to obtain a balance of glass properties. Since the primary chemical constituents of high-level radioactive waste are alumina (Al_2O_3), iron oxide (Fe_2O_3), and manganese dioxide (MnO_2), addition of high-level radioactive waste to borosilicate glass frit enhances the (short-term) durability of the product. When waste loadings of 40% or more are reached, the glass structure is so perturbed that rearrangement of atoms into more stable crystalline structures with accompanying changes to the chemical composition of the remaining glassy phase is favored. For this reason, lower limits on waste loading levels are employed. Effects of waste constituents on important glass processing and product properties are shown in Table I.

EVOLUTION OF WASTE GLASS FORMULATION AT DWPF

The primary objective of the DWPF is to convert the liquid HLW slurries to a stable borosilicate waste glass. By itself, the waste would not form a glass when heated to 1150C. Thus, frit* will be added to the waste in the DWPF in order to achieve a mixture which will form a glass. On an oxide weight basis, DWPF glass will consist of approximately 64% glass frit and 36% waste feed of which 28% is sludge and 8% is a precipitate stream containing much of the Cs-137 radioactive species. This stream is also called precipitate hydrolysis aqueous (PHA). The glass frit and the PHA together make up what is called the glass-former composition.

The glass-former composition* for the DWPF has been developed so that the DWPF waste glasses will have similar properties to simulated waste glasses based on "Frit 165", which is a frit developed for sludge - only processing (early DWPF flowsheets were based on immobilizing only the sludge fraction in the waste tanks). This sludge-only frit was designed to immobilize the full range of sludges contained in the SRS Tank Farm, and be tolerant of variations in waste composition.

In general, the SRS has followed a "system approach" in developing waste glass compositions. This approach balances glass durability against process reliability. Thus, an optimal composition is defined as one which combines desirable product properties with process properties which lead to uninterrupted processing. The primary product property considered is the durability (stability of the glass toward reaction with water). The primary processing properties are the viscosity, liquidus temperature, and waste solubility. Both the viscosity and waste solubility have product implications: glass viscosity affects the ability to fill the canister and waste solubility affects the thermal stability of the glass. In the approach taken at the SRS (8), an optimum frit is defined as one which maximizes waste solubility (by minimizing liquidus temperature), yields minimal leaching based on a standard leach test, and which yields a glass viscosity within the desired range for the DWPF melter (20 to 100 poise at 1150C).

For the frit selected for sludge-only processing, a self-directed optimization procedure was used to reach a "best" composition. An initial series of twelve frits was selected. Since the glass frit must accommodate the entire range of waste compositions, each frit was tested by preparing melts containing the test frit and the extreme waste composition which is most likely to cause the frit to violate one of the criteria above (PUREX waste for durability and waste solubility, Heavy Metal (HM) waste for viscosity). The melting temperature, 1150C, and

waste concentrations were held fixed at values used for development of the Environmental Assessment (EA) glass.

Data was collected on waste glasses made from the first 12 frits and the frits were then ranked by using a desirability coefficient which objectively weighted each of the criteria. The four worst compositions were replaced with four new compositions. The four new compositions were treated in the same way as the previous twelve, and a new ranking was then developed . While the methodology works by examining the worst frits, the end result is reached by examining the best. This process was concluded once it became clear that the region of best composition was not changing significantly. This occurred after the third round. By this time twenty frits had been studied.

The data representing these frits served as the basis for the final step, the proposal of an "optimum" frit. The compositions and properties were examined to determine the effects of each component. In general, higher amounts of silica and zirconia improved durability, but also increased viscosity. The higher viscosity is best compensated by increasing lithia relative to soda since lithia is a more effective flux and has a less deleterious effect on the leach rate. Lanthanum oxide had no clear-cut benefits to recommend its inclusion, and significantly increased the liquidus temperature. Boric oxide, magnesia and titania had relatively smaller effects on the measured properties.

These trends were used to produce five candidates for the "optimum". These frits were tested in the same manner as was done during the statistically-designed portion of the experiments. Three of the five were better than the best of the frits from the statistically-designed tests. These three were so similar in desirability coefficient and in their individual properties that an additional test to choose between them was needed. The test used was a simple side-by-side comparison of their resistance to devitrification.

Each of the final candidate frits were used to prepare waste glasses using a simulated waste composition similar to that in the DWPF Environmental Assessment (9). The EA glass composition was also tested. After melting at 1150C, all of the glasses were cooled in a manner which simulated the behavior in the center of a DWPF canister after filling with glass. Glass in this location sees the slowest cooling rate and spends the longest time between the liquidus temperature and the glass transition temperature. It represents the worst case for crystal formation. The results of this experiment showed that the EA glass contained the most crystalline material. For Frit 165, the best of these compositions, only a few small well-separated crystals could be found. As a result of this test, Frit 165 was selected as the frit composition for sludge-only processing.

This composition (Frit 165) has successfully been used both in tests with actual waste simulating natural environments, and in in-situ experiments in granite, salt, and clay. In all cases, this glass performed better than any of the other high-level waste glasses tested (including some that were melted at higher temperatures). For this reason, when the precipitation process for decontamination of high-level waste salt was adopted at SRS, the glass-former composition was modified to achieve a family of glasses as similar to 165-based glasses as possible. This was called Frit 200. This was achieved by removing some of the boron and alkali from the glass frit composition to take into account additions of these chemicals from the precipitation process. Similarly, when it became

apparent that additional sodium hydroxide and nitrite would be added to the waste as inhibitors to reduce waste tank corrosion, further reductions in the amount of alkali in the frit were made (Frit 202). The evolution in glass frit composition from that used for the EA glass, and that which will be used initially in the DWPF (Frit 202), is shown in Table II.

Table I

Table II

CONCLUSION

Borosilicate glass is not just one glass composition but is instead a family of compositions whose primary glass-forming ingredients are boron and silicon. The design and selection of the optimum glass composition is determined by the desired waste loading, then composition of the high-level radioactive waste, and processing considerations.

Whenever major changes are made to the vitrification process, the composition of the waste stream undergoes a significant change, or some other valid reason; the borosilicate glass composition can be tailored to maintain the optimum balance of all important glass properties including viscosity of the glass melt, glass liquidus temperature, and glass durability.

CONSTRUCTION OF A VITRIFICATION FACILITY

Stephen R. Barnard
West Valley Nuclear Services Co., Inc.
West Valley, NY

ABSTRACT

The Vitrification Facility at the West Valley Demonstration Project (WVDP) is comprised of the buildings, equipment, components, and

utilities that will be used to solidify (vitrify) high-level radioactive waste into stable glass logs contained within stainless steel canisters. Due to the unique nature of the WVDP and the vitrification process, construction of the necessary facilities presented distinct challenges in the areas of new facility construction and existing facility renovation. This paper will focus on construction of the vitrification facilities, which includes a shielded trench and piping to transfer High-level Waste (HLW) to a shielded cell where it will be vitrified and a system to remove nitrous oxide from the waste gas (Ex-cell Off-gas System). These facilities were constructed using unique techniques in order to allow pretreatment of the low-level waste and the vitrification development programs to continue uninterrupted.

Construction of the vitrification facilities was completed in four major phases over six years. The first phase was civil/structural construction, completed in 1990. This construction included the Crane Maintenance Room (CMR) for maintaining the process cranes, a tunnel to transfer glass canisters from the cell to the interim storage area (Transfer Tunnel), a Secondary Filter Room (SFR) housing the secondary filtration system and main exhaust fans, a Diesel Generator Room (DGR), the Cold Chemical (CC) Building to mix radiologically cold chemicals, and portions of the Shielded Vitrification Cell. The second phase was also civil/structural construction and that was completed in 1991. This effort consisted of the HLW Transfer Trench and completion of the 1.2 meter-thick concrete shielding walls for the cell called Wall Modules. In addition, the existing steel building was modified to include more square footage and additional floors. The third phase, completed in 1994, included mechanical construction, instrumentation and controls (I & C), and electrical installation. This work consisted of installation of all equipment, instrumentation, and electrical wiring and cabling for the facility, as well as installation of the final two wall modules. The fourth phase included construction of the Ex-cell Off-gas Facility that was completed June 1995. This construction phase involved converting a portion of an existing building to treat process melter off-gases.

INTRODUCTION

The WVDP is the site of a former commercial nuclear fuel reprocessing facility that operated from 1966 through 1972. In 1980, the West Valley Demonstration Project Act was signed by the president of the United States to become Public Law 96-368. The Act directs the Department of Energy (DOE) to, among other things, solidify the high-level waste stored at the site into a durable, solid form suitable for shipment to a federal repository; to clean and close the facilities used; and to dispose of the low-level and transuranic wastes collected during Project operations. The DOE began managing the WVDP in 1982 with West Valley Nuclear Services (WVNS) Co. Inc. selected as the management and operating contractor. Approximately 2,270 cubic meters of high-level nuclear waste remained in the underground steel tank within a concrete vault at the start of the Project. The waste, the result of nuclear fuel reprocessing operations, was composed of two layers; a bottom sludge and upper liquid layer. The liquid has been processed into cement-filled drums and is stored on site, leaving the sludge to be processed and poured into stainless steel canisters.

The Vitrification Facility was constructed between the Tank Farm, where the waste is stored, and the existing nuclear fuel reprocessing building. Thus incorporating the area being used for development testing called the

Component Test Stand (CTS) in the process. Figure 1 is an artist's rendering of the Vitrification Facility. It was in this area that most of the major construction took place.

Fig. 1

PHASE 1 - CIVIL/STRUCTURAL INSTALLATION CONTRACT

The civil/structural construction contract focused on two areas. The first area was located between the CTS and the existing reprocessing building. This area contained portions of the Vitrification Cell, Transfer Tunnel, Secondary Filter Room, HVAC Control Room, and the Crane Maintenance Room. All of these areas are shielded and built to withstand a seismic event; thus the bulk of the construction work was in the form of heavily reinforced concrete floors, walls, and ceilings. Problems to contend with included: 1) working around contaminated buildings and soil near the existing process building 2) avoiding guy wires from the main exhaust stack 3) working around scheduled transfers of radioactive liquid to the Cement Solidification System (CSS) through the trench located in the area 4) inclement weather and 5) providing continuous access to the test facility.

The conversion of the CTS to what is now known as the Vitrification Cell was accomplished in phases in order to: minimize construction and testing interferences, permit some concurrent development/operations and construction work, and fit the delivery dates of government furnished equipment. Near the end of Phase 1, testing was completed and the CTS was dismantled. The test melter, associated piping, electrical systems, and equipment were removed. This effort required close coordination among two subcontractors and WVNS personnel. Some of the equipment was salvaged to be installed in the new facility.

One of the unique construction features of the Vitrification Cell was the wall modules. These special walls were fabricated off site to facilitate continued testing and were installed between the concrete roof and columns that had been installed before testing started. Soon after the CTS was dismantled, five of the seven wall modules were installed. These large stainless steel modules (averaging 4.7 meters wide by 7.1 meters high by 1.2 meters thick) were prefabricated in a vendor's shop complete with all shielded piping and electrical penetrations, window liners, and manipulator and shield plug ports. The installation included adding reinforcing bar (or rebar), which was tied to the existing columns using threaded rebar screwed into embedded couplings in the columns. The installation of these prefabricated modules was successfully completed as planned and saved a considerable amount of time.

Eight radiation shielding doors were installed as the construction proceeded. The largest of these shield doors, a 105-ton CMR door, required using a 350-ton mobile crane. This was problematic due to the small working area: the crane had to be positioned between the west side of the Vitrification Building, the stack's guy wires, and the Cold Chemical Building excavation.

The second major focus of Phase I construction included areas west of the CTS, where the Cold Chemical Building was built. This building houses tanks, pumps, and grinders used to mix the chemicals and glass formers before they are pumped to the Vitrification Cell to be mixed with the radioactive sludge. It is a structural steel building with a metal skin. The bottom floor is concrete with curbs and sumps to contain potential chemical spills. The second floor is steel with grating around the tops of vessels. Completion of the structural steel portion of this building

was delayed until the dismantling of the temporary cold chemical system, because the existing tanks were to be used for the final system. The tanks were installed as the building was erected.

PHASE 2 - CIVIL/STRUCTURAL MODIFICATION CONTRACT

This civil/structural construction contract modified the CTS Building to bring it to its final configuration and allow for installation of the process equipment. Specifically, it modified the structural steel building, added more floor space, and installed underground fire sprinkler mains and floor drains. This portion of the work was relatively straightforward in that the WVNS Construction Department controlled the area and no operational facilities were adjacent to the CTS Building.

The wall modules, installed by the first contract, had a stainless steel face on the radioactive or "hot" side of the cell wall to be used as the interior form work for placing concrete. The unique portion of this work was placing concrete in these wall modules. See the photograph in Fig. 2.

Fig. 2

WVNS and the DOE consulted with the US Nuclear Regulatory Commission (NRC) on the issues involved in forming the wall modules. All parties were interested in developing a method of concrete placement that would ensure no voids within the concrete interior of the wall modules. It was decided to construct a prototype wall to demonstrate the placement of the specially developed concrete mix. The concrete was placed in the prototype wall, with the procedures and techniques used for placement being carefully watched and critiqued. The wall was then evaluated by destructive examination and this indicated that the concrete did flow around the numerous wall penetrations. The actual placement of concrete in the modules progressed well as a result of the lessons learned from the prototype.

The other major portion of this contract installed the HLW trench that extends from the Waste Tank Farm to the Vitrification Cell. This trench consisted of a 0.31 meter-thick concrete floor, 0.5 meter-thick concrete walls, and 0.61 meter-thick removable concrete covers. The floor and walls were cast-in-place using conventional form work. In addition, there were four concrete valve and jumper pits constructed adjacent to the trench.

The concrete covers were fabricated off site at a precast concrete contractor's shop. There were several different sizes and shapes that were cast in custom steel forms. The quality of these covers was acceptable, with tight dimensional accuracy. The covers fit the cast-in-place concrete trench with only minor grinding.

PHASE 3 - MECHANICAL, I & C, ELECTRICAL INSTALLATION CONTRACT

This mechanical, I & C, and electrical construction contract installed all of the In-cell process equipment including vessels, jumpers, pipes, the Off-gas system, the ventilation system, and the electrical systems. The contract also installed all the controls, electrical, piping for utilities, and equipment located outside the cell to support and operate the In-cell processes. See Fig. 3.

Fig. 3

The layout of In-cell process equipment provided some opportunities for innovative installation methods. One method required the installation of 60 stainless steel pipes and conduits from the hot face of the cell wall to the stub wall. The hot face of the cell wall and the stub wall are perpendicular to each other and the space allocated for this installation was 1.0 meter from the hot face by 3.3 meters from the stub wall by 2.0

meters high. Approximately 120 field welds were made in this area. The sequence of installation was critical: one pipe installed in the wrong sequence could make it difficult to install additional pipes at a later date.

Many areas of the Facility had been modeled three-dimensionally on a computer to check for interferences. It was decided to use this modeling to create the isometric drawings and provide them to the subcontractor. Using this approach saved several weeks in the planning and approval cycles, and allowed the cell equipment to be installed earlier than scheduled.

The HLW transfer pipe was also installed in the HLW trench as a part of this contract. The trench is 152 meters long and from 0.6 to 1.8 meters wide. There are 762 meters of Schedule 40 stainless steel transfer pipe encased by a Schedule 40 stainless steel guard pipe. The pipe was placed in the trench on multiple layers of pipe supports with tight tolerances and critical slopes for drainage. This work required careful planning to ensure that 100 percent of the transfer pipe joints could be radiographed. The installation and field radiography took place in a physically tight area that required confined space entry qualified personnel.

The final seismic evaluation caused some redesign of the transfer piping in the HLW transfer trench. This was done before the subcontractor began shop fabrication of the transfer pipe, thus minimizing the impact to the overall schedule.

After all of the piping was installed and inspected, the trench covers were placed on the trench, the joints caulked, and the covers and upper side of the trench insulated.

PHASE 4 - EX-CELL OFF-GAS FACILITY CONTRACT

The Ex-cell Off-gas Facility construction contract modified and added to the existing 01-14 Building to create a NOx Abatement Facility. The existing building was made of reinforced concrete and included hot cells, ventilation room equipment, controls, and on-going processing of liquid waste. The contract additionally included modification of the Off-gas trench to accommodate the Off-gas pipe. This trench was also used for shielding the liquid transfer line. See Fig. 4.

Fig. 4

Building construction was one of the most challenging parts of the Project. The challenge arose because one half of the building was being used by Operations to process liquid, waste and the Off-gas trench was being used for transferring liquid waste. The utilities and controls were located on both sides of the building and careful scheduling and coordination were necessary to allow production to continue. This construction included the challenge of sequencing the demolition of various systems during operations and relocating operating systems with only short duration shut downs. Also, the building expansion took place in the winter and construction areas had to be winterized with temporary heat and additional shelters erected. Maintaining access was difficult, and it became necessary to install more stairs, walkways, heating systems, and lighting.

Most of the construction in this phase was performed in a radiological buffer area. Other hazards associated with this phase of construction included asbestos abatement of insulation around vessels and roof penetrations, excavations in radiologically contaminated areas, installing fasteners in contaminated concrete, performing 25 radiological

hot taps, and performing the majority of work in confined spaces, as required by DOE Orders, consistent with the Occupational Safety and Health Administration (OSHA) requirements. Furthermore, all crane work had to be sequenced carefully to accommodate limited operating areas and areas which that populated by workers.

Safety

Personnel safety has always been of prime importance at the WVDP. During Construction of the Facility, the Construction Safety Department continually strove to improve the safety of all personnel. In 1994 and 1995, during the peak building period, construction safety at the WVDP had one of the lowest Total Recordable Case Rates (TRC) of any active DOE site; finishing 1994 with a TRC of 3.34 and 1995 with a TRC of 3.44. This is significantly less than the construction industry average of 12.2 and the DOE construction average of 7.5. The overall TRC for all construction on this Project, including subcontractors, is 4.9. This figure represents 11 years and 2.5 million person-hours.

Many factors have led to the outstanding safety record in construction at the WVDP. Listed below are some of the specific factors and actions taken to enhance the safety performance at the WVDP:

All parties on site, from DOE to the smallest subcontractor, are involved in site programs to achieve a total safety culture.

Construction safety has developed a subcontractor safety training checklist that identifies the prerequisite safety training a subcontractor must complete before working on site. Subcontractor safety records are reviewed monthly using this checklist.

Construction and subcontractor safety personnel perform daily walkdowns of construction areas to identify safety hazards. Safety inspections of each subcontractor are performed weekly to a pre-existing checklist to monitor each subcontractor's program.

WVNS Construction Department, WVNS Industrial Hygiene and Safety Department, and subcontractor safety professionals meet monthly to discuss relevant safety issues. These meeting have been very instrumental in identifying and correcting safety issues and concerns expeditiously.

All WVNS construction personnel have been trained in OSHA hazard recognition and instructed to look for hazards during the course of their daily duties. They have been instructed to correct hazards when possible or to report hazards to the appropriate safety professional or WVNS management.

WVNS encourages construction subcontractors to give proper attention to safety. To reinforce this, WVNS requires direct daily communication with the subcontractors' safety persons on safety issues; this includes written records of corrective actions on surveillance items and formal critiques for any event that is defined to be reportable.

CONCLUSION

Construction of all vitrification-related buildings and areas was a unique and sometimes difficult project due to the Project guidelines requiring the conversion of existing facilities, and because of the concurrent vitrification process development, testing, and operations that were occurring during construction. The Construction Department developed unique methods to complete projects and maintain schedules. The significant focus on safety as a culture yielded excellent results, with all parties having a safe work ethic and clearly committed to having a safe work environment.

The actual cost of the vitrification facilities construction closely paralleled the Total Estimated Cost (TEC) for the Project established in 1988. The TEC was $122M and the final cost was $127M; representing only a four percent escalation in cost.
Work continues to tie-in radioactive lines from the Waste Tank Farm to nonradioactive piping in the Vitrification Facility and adjacent structures. Radioactive operations are scheduled to commence in June 1996.

DEPARTMENT OF ENERGY REMOTE-HANDLED TRANSURANIC WASTE FACILITY CHARACTERIZATION CAPABILITY ASSESSMENT

Kenneth Guay
Carl Hess
Thomas Johnsen
S.M. Stoller Corporation
Oak Ridge, Tennessee

ABSTRACT

The Department of Energy (DOE) currently stores remote-handled (RH) transuranic (TRU) wastes at seven sites across the complex. It plans to ship this waste to the Waste Isolation Pilot Plant (WIPP) in Carlsbad, New Mexico for disposal. This requires the waste to be packaged and characterized to meet the WIPP Waste Acceptance Criteria (WIPP-WAC) and applicable transportation requirements. This study was conducted to assess both existing and future capabilities for characterization of RH TRU waste at the seven DOE sites that store these wastes. The characterization methodologies assessed included process knowledge, radioassay, radiography, visual examination, and chemical analysis. The study concluded that the current infrastructure for RH TRU waste characterization will not support certification to the WIPP-WAC. Although the WIPP-WAC for RH TRU waste is not finalized and the associated requirements are not completely known, it is reasonable to assume that the final requirements will be at least as rigorous as those for contact-handled TRU waste. Therefore, considerable progress must be made to improve current capabilities for RH TRU waste characterization, particularly for nondestructive assay and nondestructive examination where there is limited capability.

INTRODUCTION

The Department of Energy (DOE) currently stores remote-handled (RH) transuranic (TRU) wastes at seven sites across the complex. These sites include the Argonne National Laboratory-East (ANL-E), Argonne National Laboratory-West (ANL-W), the Hanford Site (HANF), the Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), and Oak Ridge National Laboratory (ORNL). The current inventory of stored RH TRU waste is approximately 1,600m3, with over 60% of the volume residing at ORNL (1). An additional 3,480m3 of RH TRU waste is also projected to be generated at the above sites over the next several years, primarily from remedial activities. Recently, HANF alone has projected approximately 3,000m3 of RH TRU waste, about 85% of the total forecasted. TRU waste is defined by DOE Order 5820.2A as all radioactive waste that contains greater than 100 nanocuries of alpha-emitting isotopes with atomic numbers greater than 92 and half lives greater than 20 years per gram of waste (100 nCi/g). RH TRU waste is any TRU waste with a radiation dose rate measured at the surface of the waste container greater than 200

mrem/hr. DOE currently plans to ship all RH TRU waste to the Waste Isolation Pilot Plant (WIPP) in Carlsbad, New Mexico for disposal. DOE is required to repackage, characterize, and perhaps treat much of the waste in order to meet WIPP Waste Acceptance Criteria (WIPP-WAC) and applicable transportation requirements.

RH TRU waste exists in solid, liquid, and sludge form. Most of the waste will require repackaging and further characterization before it can be shipped to WIPP for disposal. The RH TRU wastes that require repackaging are either stored in containers not suitable for either transportation or for handling at WIPP (i.e., concrete casks and large storage tanks). They also may require visual inspection and sampling for verification of process knowledge. Some wastes such as sludges are stored in large tanks that may require treatment to meet the WIPP-WAC or other applicable requirements to achieve more stable waste forms.

Due to the high radioactivity and its impacts on operational safety, characterization of RH TRU waste is particularly challenging. Characterization methods used to sample and analyze the waste must be developed to ensure the quality standards are acceptable to the Environmental Protection Agency (EPA). Following evaluation and acceptance of these methods, WIPP documentation including the Quality Assurance Program Plan (QAPP), Sampling and Analysis Guidance Manual, and the Performance Demonstration Program must be revised to incorporate the requirements at each DOE generator/storage facility.

Characterization of RH TRU waste likely will require a substantial portion of the resource commitment by DOE to prepare these wastes for disposal at WIPP. This study was conducted to assess both existing and future capabilities for characterization of RH TRU waste at the seven DOE sites that store these wastes. By comparing this study with the RH TRU waste characterization requirements currently under development, DOE will be able to assess needs and generate plans for system-wide development to support adequate characterization of all stored and projected RH TRU wastes.

CHARACTERIZATION REQUIREMENTS

Adequate waste characterization data for RH TRU wastes must be collected from the DOE sites so WIPP can demonstrate compliance with applicable regulations for the total disposed inventory. Any site that does not provide sufficient waste characterization information will not be eligible to send its waste to WIPP for final disposal. For consistent RH TRU categorization, TRU waste should be correlated to the Waste Matrix Codes established by DOE as acceptable to the WIPP facility. This task, along with other tasks, should be accomplished through implementation of the DOE TRU Waste QAPP. The characterization program should address the data needs associated with regulatory compliance programs listed below.

Performance Assessment - Evaluation of long-term radionuclide containment (40 CFR191).

Land Disposal Restrictions (40 CFR 268.6) - Containment of hazardous constituents.

General Waste Analysis - Verification of waste characterization data [40 CFR 270.14(b)(2) and 270.23(c)].

Transportation of Radioactive Waste - Approval of the Safety Analysis Report for Packaging of the RH TRU shipping cask (10 CFR 71).

Compliance Criteria (40 CFR 194).

CHARACTERIZATION METHODS

RH TRU waste characterization refers to the examination and sampling and analysis of the waste and to the inspection of waste generation records as a means to demonstrate compliance with the requirements of applicable regulations.

Process Knowledge: Process knowledge is the ability of waste generators to use their understanding of an operation to characterize the various components that make up a given waste stream. Process knowledge is the least costly method of waste characterization and does not subject facility personnel to radiological or other operational risks. Because of the particularly high contact radiation levels and inherent handling risks associated with RH TRU waste, process knowledge will play an important role in the overall characterization process.

Radioassay: The Nuclear Regulatory Commission has identified radioassay as an acceptable technique for the identification of radionuclide contents of a RH TRU waste container. Numerous radioassay techniques are available to determine the TRU content of bulk waste. Radioassay methods may include both nondestructive and destructive techniques. Nondestructive radioassay capability needs to be developed for RH TRU waste.

Radiography: Radiography is a nondestructive qualitative and "semi-quantitative" (i.e., used to estimate the volume of free liquids that might be present in within the waste matrix) technique that involves X-ray scanning of waste containers to identify and verify waste container contents. Real-time radiography (RTR) has been developed by DOE specifically to aid in the examination and identification of containerized waste. There is no equivalent or associated method found in EPA sampling and analysis guidance documents.

Visual Characterization: The visual examination of the contents of a waste container is designed to provide data on the type and amount of material in each of the waste containers. Visual examination is an analytical process that does not involve sampling procedures. The technique provides a compliance assessment of the waste contents with respect to the WIPP-WAC. It also verifies process knowledge and physical waste form and determines whether detectable free liquids are present in the waste contents. Also, the results of radiography can be verified through visual examination of a statistically selected number of waste containers from each waste stream.

Chemical Analysis: About 45% of the RH TRU waste volume is "mixed" waste containing both radioactive and hazardous constituents that are regulated under the Resource Conservation and Recovery Act (RCRA). Examples of mixed waste are radionuclide-contaminated spent solvents, discarded materials contaminated with both solvents and radioactive material, scintillation fluids, and discarded contaminated lead shielding. A determination of the analysis requirements for RH TRU waste must identify the appropriate methodologies that are required for sufficient characterization (process knowledge, sample and analysis, etc.).

RH TRU WASTE INVENTORY

RH TRU inventory data in this report were taken from the WIPP Transuranic Waste Baseline Inventory Report (WTWBIR), which establishes a methodology for grouping wastes of similar physical and chemical properties (1). The wastes are grouped into a series of "waste profiles" that can easily be disseminated to regulatory agencies and other stakeholders. The WTWBIR is also used as the basis for radiological source term data for the WIPP Performance Assessment and for hazardous waste source term data used in

the WIPP RCRA Part B Permit and No Migration Petition. Table I summarizes the stored and projected inventory of RH TRU waste at each of the seven sites assessed.

Table I

SITE ASSESSMENTS

Facilities required for the characterization of RH TRU waste should be capable of activities such as removing, sorting, treating, repackaging, visually characterizing, certifying, nondestructive assaying, and examining containers of either solid or liquid/sludge waste streams. This study compiled data provided by the DOE sites that have RH TRU waste in storage and are projecting future generation.

Argonne National Laboratory - East: ANL-E occupies a 1,700 acre tract in DuPage County, Illinois, located southwest of Chicago. ANL-E is a DOE energy research and development laboratory that conducts a broad program of energy related sciences and serves as an important center for the study of nuclear and non-nuclear energy sources (2). RH TRU waste is generated at ANL-E from fuel examination activities at the Alpha-Gamma Hot Cell Facility (AGHCF) and is placed in metal cans, bagged-out and heat-sealed, and packaged in Department of Transportation Specification 7A 30-gallon drums. ANL-E has an RH TRU waste certification plan for shipment to WIPP but a revision to the current WIPP-WAC, Revision 4 is needed (3) . ANL-E has no planned or current facility to load RH TRU waste in canisters (for approved WIPP casks). They, therefore, will continue to ship RH TRU waste to the INEL for interim storage. ANL-E has no plans for facility modifications, new facilities, or new capabilities for characterization of RH TRU waste.

ANL-E does have two facilities that may be used for the characterization of RH TRU waste: the AGHCF and the Building 200 Hot Cell Facility. The 10,000-ft3 AGHCF complex is designed for metallurgical research and consists of a multicurie hot cell, the Electron Beam Laboratory, a small machine shop, and a decontamination/repair area (4). The hot cells contain a total of ten work stations fitted with viewing windows and equipped with master-slave manipulators. Primary auxiliary equipment at the AGHCF could be used in the examination of RH-TRU waste. It was used previously to examine and repackage 30-gal drums of RH-TRU waste. The Building 200 Hot Cell Facility consists of 2 floors of shielded cells, 12 isolated hot laboratories, and a shielded corridor for movement of highly radioactive materials between cells. A cell on the lower level was previously used for the packaging of RH TRU waste and shields against 50,000 Ci of 1-MeV gamma radiation. Two mobile and two bridge-mounted remotely-controlled polar manipulators are also available for use in areas not accessible to the master-slave manipulators.

Argonne National Laboratory - West: ANL-W is situated in the extreme southeastern portion of the INEL and has had a primary mission to develop the Integral Fast Reactor concept (2). ANL-W is an RH TRU waste generator at the INEL and has developed a RH TRU waste certification plan to document the activities necessary to characterize and certify RH TRU waste for disposal at WIPP (5). ANL-W has also completed a preliminary Data and Process Knowledge Assessment to determine the extent of the INEL's RH TRU waste that can be certified for WIPP disposal without additional characterization activities.

Two facilities at ANL-W could be used for the characterization of RH TRU waste: the Hot Fuel Examination Facility (HFEF) and the Fuel Cycle Facility (FCF). HFEF is comprised of two adjacent, shielded hot cells

that include a decontamination cell and a main cell. The main cell uses a high purity argon gas designed for containment of plutonium contamination and is arranged for vertical handling, examination, and cutup of long experiments up to 30 feet in length. The cell is designed for long-term, permanent, remote operations that do not require personnel entry. The decontamination cell is air-filled and used for the handling of irradiated experiments, the decontamination of hot cell equipment, and the loading and shipping of radioactive waste generated at the facility. Much of the in-cell examination equipment for fuel elements is automated or semi-automated. The FCF also has two adjacent cells that include an argon cell and an air cell. The 16-sided FCF argon cell was modified to support the new remote reprocessing and refabrication fuel cycle process for the former DOE Integral Fast Reactor Program. This program has since been discontinued by DOE, effectively ending the current mission of FCF. ANL-W is currently developing nondestructive assay (NDA) techniques for fast and low-cost assay of nuclear materials. These passive and active techniques are based on specific signatures of elemental/isotopic materials contained in certain waste streams and spent fuel. The techniques will be suitable for waste streams exhibiting high radiation, that contain nuclear poisons, (a,n)-sources, and lumped fissionable material in a heterogeneous matrix. The currently designed system is equipped with a 14 MeV, source providing 1011 neutrons per second during the active phase.

Hanford Reservation: HANF is located in the southeast corner of Washington State, approximately 50 miles north of the Oregon border. HANF is located in a structural and topographic depression of the Columbia Plateau called the Columbia Basin. HANF covers an area of about 560 square miles of semiarid land. The mission is to cleanup HANF, to provide scientific and technological excellence to meet global needs, and to be a partner in the economic diversification of the region (6). The retrieval and characterization of the existing RH TRU wastes at HANF will not occur before the year 2000, the earliest expected startup date of the Waste Receiving and Packaging Plant (WRAP) Module 2B. Until that time, the data supplied will be based on available engineering judgement and process knowledge.

HANF does not have existing facilities capable of characterizing the RH TRU waste currently stored at the site. Capabilities for nondestructive examination (NDE) and nondestructive assay (NDA) for contact-handled (CH) TRU waste characterization are available, but they are not readily adaptable for RH TRU. The planned WRAP Module 2B is a major line item construction project at HANF that will enable characterizing and processing RH TRU waste for shipment to WIPP (7). WRAP Module 2B will be a largely remotely-operated hot cell facility with moderate shielding requirements for RH wastes having contact radiation levels of up to 100 R/h. The facility will process the retrievably-stored RH TRU wastes and the projected RH TRU wastes that will be generated by future HANF programs.

The current concept for the WRAP Module 2B consists of a large process hot cell used for the disassembly and size reduction of large items. Adjacent to this cell are several small cells to provide for sorting, treatment, and packaging of the waste into containers. HANF plans an engineering study to determine the size of the main hot cell, the number of processing cells, and other conceptual functional elements associated

with the facility. WRAP Module 2B will have capabilities for visual examination, direct sampling, and NDE and NDA of RH TRU waste.

Idaho National Engineering Laboratory: The INEL covers approximately 890 square miles and is located near Idaho Falls, Idaho. It was established in 1949 to conduct, test, and operate nuclear facilities. Interim storage of RH TRU waste was initiated at the INEL in 1976 with the establishment of the Intermediate-Level Transuranic Storage Facility (ILTSF), located at the Radioactive Waste Management Complex (RWMC). The ILTSF was established for retrievable storage of RH TRU waste with radiation levels greater than 200 mR/hr and less than 4,500 R/hr. The INEL has also developed a test plan for headspace gas sampling of drums in a cooperative venture with ANL-E. Although no gas sampling activities have been initiated, the methodologies have been established and much of the associated operating and design documentation developed.

The INEL does not have facilities that are currently capable of characterizing RH TRU waste. The Stored Waste Examination Pilot Plant which is located at the RWMC, could be adapted for RH waste with the addition of shielding, and remote-handling equipment and with modification to the NDA measurement system and computer algorithm. Hot cell facilities at the INEL are located at the Test Area North and Test Reactor Area. These facilities may have potential application for visual characterization and direct sampling of RH TRU wastes. No descriptive information of these facilities and their current capabilities, however, could be obtained from the INEL.

The INEL is currently developing systems that will enable "at-line" headspace gas sampling of TRU waste drums. Included are a permanently installed monitoring system at the INEL Drum Venting Facility at the RWMC and the development of a portable system that can be transported on-offsite for at-line sampling. The INEL is also preparing a proposal to request funding to support completion of a mobile gas sampling and vent installation station for RH TRU waste drums.

Los Alamos National Laboratory: LANL is located in north-central New Mexico, north-northeast of Albuquerque. Since its inception in 1943, the primary mission of LANL has been the research and development of nuclear weapons. Programs include weapons development, nuclear fission and fusion research, nuclear safeguards and security, and verification and control (8). All of LANL RH TRU waste is generated by the destructive examination of experimental fuel elements from the Experimental Breeder Reactor-2, including segments of fuel discarded after metallurgical examination (9). Over the past year and a half, LANL has been characterizing and packaging RH TRU waste for ultimate disposal at WIPP. To date, 16 WIPP-approved canisters have been characterized, packaged, and placed into retrievable storage. LANL has pioneered much of the radioassay capabilities that are currently in use at many DOE sites, and it continues to research and develop additional technologies. LANL currently has the only system used in the DOE complex that is capable of assaying RH TRU waste. It was designed to specifically measure waste cans having a diameter of 21-cm and a height of 30-cm, with an overall waste volume of approximately 1-gal. The RH assay system chamber size could be increased to accept drum sizes up to 55-gal.

The LANL Chemical and Metallurgy Hot Cell Facility is a complex of 16 cells comprised of 2 banks of 8 hot cells (10). Each bank of eight hot cells has a central corridor and hydraulic-actuated doors to isolate each

cell from the corridor. The corridor has enough space to accommodate 55-gal drums, shielded waste casks, or larger overpacks.

A major LANL research and development project for TRU waste characterization is the Combined Thermal/Epithermal Neutron (CTEN) Interrogation radioassay device. According to LANL researchers, this device is highly suitable for determining the fissile content of cans of RH TRU waste derived from irradiated breeder reactor fuel pins that emit gamma radiation levels of up to 1,000 R/h (11). LANL has made significant progress towards development of a CTEN interrogation unit capable of full-scale operational applications. A fully-operational CTEN instrument that is capable of assaying both 55- and 83-gal drums has been constructed.

Oak Ridge National Laboratory: The 8,771 acre ORNL is located on the Oak Ridge Reservation and is situated almost entirely within the 6.5-square mile White Oak Creek drainage basin. ORNL's mission is to conduct research and development activities for DOE and other government agencies, as well as for private institutions (12). Over 60% of the total DOE RH TRU waste inventory is stored at ORNL.

In the late 1980s, ORNL developed a strategy to process and repackage its stored RH TRU waste that included the proposed TRU Processing Facility (TPF), a major line-item project at ORNL that was originally conceived as the Waste Handling and Packaging Plant (13). To assist in the development of the TPF, ORNL has completed a study of existing documentation to characterize much of the stored RH TRU waste through process knowledge (14). An alternative to TPF is the feasibility of using existing facilities to process TRU wastes. A report describes the existing facilities and technologies considered, the business management methods evaluated for cost effectiveness, processing schedules, life-cycle cost estimates, and final recommendations.

A real-time NDA and NDE system for compliance verification with WIPP-WAC requirements (e.g., fissile material limits and free liquids or particulates) is essential to the TPF. After review of the NDA and NDE techniques applicable to CH TRU wastes, ORNL has concluded that a linear accelerator- (LINAC) based system is likely to succeed in meeting the WIPP-WAC requirements. Development of NDE by LINAC-based RTR is nearly complete, whereas a LINAC system to perform radioassay is in the early stages of development.

Building 3517 (the Fission Product Development Laboratory) is a two-story structure constructed of masonry block, structural steel, and reinforced concrete, with a metal-sided high bay area over the cell bank. The building structure serves as a secondary confinement enclosure. Material receiving and shipping for the cells is performed in a truck bay and airlock at the west end of the building. A 10-ton dolly moves material to where it can be lifted by a 20-ton bridge crane located over the cell bank. The cell roof has removable plugs for access to each cell. The cell bank consists of two rows of cells with the north row of cells divided into nine separate rooms, but all are interconnected by a pipe chase along the full height of the cell. The south row cells are each serviced by one or two windows and one or two sets of master/slave manipulator arms. The interiors of the hot cells are highly contaminated from past operations. Although the north bank of cells is currently undergoing decontamination, the south cell bank is still used for the preparation of radioisotope sources. The soil surrounding this structure is also highly

contaminated with fission products as a result of previous waste-line leaks and spills and requires remediation.

Building 3525 (the High-Radiation-Level Examination Laboratory) is a two-story brick building with a partial basement that houses ventilation equipment. Building 3525 is divided into two functional sections: the front section is a single-story office and laboratory area, and the two-story structure in the rear houses the cell complex, the operating areas, and other support functions. The primary cell structure consists of three straight-line banks that are arranged in the form of a "U" for functional purposes. The cells on this level are served by 15 viewing windows and a pair of master-slave manipulators at each window. The inside surfaces of the cell banks are lined with stainless steel sheet to provide containment of particulate matter. Special penetrations provide for the sealed entry of services, such as instrument lines, water, and gas. Within each cell bank, heavy objects are moved by electro-mechanical manipulators and a companion 3-ton bridge crane. Special penetrations in the cell wall accommodate some basic experimental equipment and shielded and sealed transfer mechanisms. These penetrations include the sleeve ports for the periscopes, the stereo-microscope, and the collimator for the gamma spectrometer. They also include openings for the transfer of samples to shielded transfer stations provided at the rear face of the charging cell (No.7). Items up to 446 ft in size and weighing up to 10 tons may also be transferred through a shielded airlock door system.

Building 7860 (the Hydrofracture Facility) is a single-story structure constructed of reinforced concrete, masonry block, and structural steel. The building is L-shaped with overall dimensions of 5679.5 ft. There is a two-story masonry block portion for an equipment room and a three-story steel-sided portion for the well pipe storage tower. The first floor consists of equipment rooms, an office, a control room, and change rooms. There are three cells in the facility: one cell containing the well head, a second cell containing two well injection pumps, and a third cell containing the mixing equipment. Access into the cells is provided through the cell roofs and a bridge crane in the well pipe storage tower. There is no secondary containment arou`nd the cells. Building 7860 was used to mix and inject liquid waste and grout into highly impermeable shale formations located 700- to 1,000-ft below the surface. The Tennessee Department of Health and Environment will not permit any further use of this disposal technique; therefore, Building 7860 is no longer in use.

Building 7930 (the Thorium-Uranium Recycle Facility) is a three-story structure with a partial basement. It is constructed of structural steel, reinforced concrete, and masonry. The building has an irregular shape, and the structure serves as a secondary confinement enclosure. The first floor provides space for technical personnel offices, operating space for cells and maintenance, a glove-box maintenance room, a receiving area, a fuel storage basin, change rooms, a compressor, CO2 storage, and elevator machinery rooms. The second floor provides space for chemical makeup, sampling of radioactive materials, a development laboratory, a shop for handling slightly contaminated material, a maintenance area, and mechanical and electrical-equipment rooms. Located on the third floor is a high bay that includes the cell roof area and provides facilities for entry of cell services and cell access. The third floor is serviced by a 50-ton bridge crane that has a 5-ton auxiliary hoist. Heavy equipment and

casks can be brought into the facility and transported by the 50-ton crane to various locations over the cell complex.

The principal cell structure is in the shape of a "T" and consists of one straight section that contains 4 cells and another section that runs at a right angle to the first section. In addition, a lightly-shielded equipment storage cell is located adjacent to and below the bulk of the cell structure. A glove maintenance room is connected to the shielded-cell system. The glove-maintenance room is accessed through an equipment airlock. The bulk of the shielding is normal concrete, 5.5-ft thick up to the second floor level around the cells and 4.5-ft thick above the second floor. Decontamination cell shielding is 4-ft thick high-density concrete or equivalent up to the second floor level around the cells and 3-ft thick above the second floor; shielding around the equipment storage cell is 2-ft thick normal concrete. Window and master-slave manipulator openings and cell services are installed at 8-ft modular intervals in the cell face.

CONCLUSIONS

This study provides an assessment of the existing and planned capabilities to characterize RH TRU waste at major DOE sites. Based on the preliminary assessment, there are limited characterization capabilities at the sites that have RH TRU waste. These findings of existing and planned DOE capabilities to characterized RH TRU wastes are summarized below and presented in Table II.

Nondestructive examination capabilities of RH TRU waste using RTR are essentially nonexistent. RTR systems located at HANF, INEL, and ORNL are capable of examining CH TRU wastes only. Application to RH wastes would require the installation of shielding and remote-handling equipment. Some sites posses other systems such as neutron radiography that would require modifications to examine RH TRU waste containers.

Visual characterization capabilities may exist at hot cells located at ANL-E, ANL-W, INEL, LANL, and ORNL. The ANL-E, ANL-W, and LANL hot cells are relatively modern facilities that would be capable of examining RH TRU wastes, but the INEL facilities are outdated and would require upgrades prior to use.

Gas sampling and analysis capabilities exist at ANL-W and INEL for CH TRU wastes. Application of these systems to RH TRU wastes require installation of additional shielding. The INEL may complete a mobile gas sampling and vent station for RH TRU waste drums that has been designed and fabricated. Some preliminary testing been performed on a prototype system.

Table II

Currently available NDA capabilities for characterizing RH TRU waste are limited.The only system capable of neutron assay of RH TRU waste is a small passive-active neutron device located at the LANL. This system is presently capable of successfully assaying only certain waste streams generated at LANL. Application to other offsite RH TRU waste streams would require extensive system modifications. Although there are new neutron interrogation assay system technologies for RH TRU waste under development at LANL and the ORNL, these systems are unproven and are probably years from potential use in an operating environment.

ABSTRACT
In March 1994, the Department of Energy Carlsbad Area Office (DOE/CAO) implemented a performance-based planning method to assist in prioritization within the Waste Isolation Pilot Plant (WIPP). Probabilistic performance calculations were required for the Systems Prioritization Method (SPM) and roughly 46,700 combinations of activities were analyzed, generating a large volume of information to be documented,

analyzed, and communicated. A self-contained information management system consisting of a relational database on a 600-megabyte CD-ROM was built to meet this need. The CD-ROM was used to store performance assessment results, data analysis and visualization tools, information about the activities, electronic copies of 40 CFR 191 and 40 CFR 268, technical reference papers, and the final SPM report. Copies of the CD-ROM were distributed to interested members of the public, WIPP participants, and the Environmental Protection Agency (EPA).

INTRODUCTION

In March 1994, DOE/CAO implemented a performance-based planning method to assist in prioritization within the WIPP project with respect to applicable EPA long-term performance requirements in 40 CFR 191.13(a) and 40 CFR 268.6 (1-5). SPM was designed to define the most cost-effective combinations of scientific investigations, engineered alternatives, and waste acceptance criteria to support the WIPP compliance certification application. Probabilistic performance calculations were required and roughly 46,700 combinations of activities were analyzed in the second phase of SPM (SPM-2). A self-contained information management system consisting of a relational database on a 600-megabyte CD-ROM was built to meet this need.

THE SPM CD-ROM INFORMATION SYSTEM

In order to make this very large volume of data available and meaningful to a wide audience, SPM-2 results were published on a CD-ROM in the form of a self-contained information system. The CD-ROM operates on WINDOWSTM platforms. To minimize incremental costs of its use, all software (except WINDOWSTM) is contained on the CD-ROM in a form that can be reproduced without violating copyright protection. A relational database on a 600-megabyte CD-ROM is used to store performance assessment results, data analysis and visualization tools, information about the activities, electronic copies of 40 CFR 191 and 40 CFR 268, technical reference papers, and the final SPM report (Fig. 1). Information contained on the CD-ROM would, if printed out, create a stack of paper over three hundred feet tall.

Fig. 1

Copies of the CD-ROM were distributed to interested members of the public, WIPP participants, and the EPA. To make the system as user-friendly as possible, the database uses a point-and-click-structure and all software needed to run the database is contained on the CD-ROM. In addition, all files are hyperlinked so that a user can explore regulatory requirementssuch as human intrusionfrom a point of origin in the Federal Regulations through their treatment in technical references. Over fifty online help panels provide introductory material on such topics as the WIPP mission, transuranic waste, performance assessment, and a step-by-step explanation of the SPM calculations. The CD-ROM also contains an online software manual and hard copy reports can be generated for each activity.

One of the objectives of the CD-ROM information system is to promote efficiency (and quality) by providing as much relevant data as possible to support users' understanding of the SPM-2 data, results, and calculations. To that end, a graphical interface is provided to orient the user and help navigate through the relational database system. In addition to providing a contextual background for understanding the meaning of data displayed on any panel, four levels of explanatory information are provided.

The Data Visualizer

The heart of the SPM-2 information system is a data visualizer containing performance measures (cost, duration, and probability of demonstrating compliance (PDC)) for roughly 46,700 programmatic options (activity sets). The data visualizer is implemented using a commercially available off-the-shelf database management system for data storage and retrieval, computations, data display, and graphical user interface.

The database management system provides interactive functions for selecting groups of activity sets for analysis and visualization based on performance measure ranges, presence or absence of particular subsets of activities in the activity sets of interest, or both. The visualization system provides six views of selected activity set groups: two-dimensional scatter charts with three-axis pairs (cost-PDC, duration-PDC, cost-duration); a three dimensional view plotting maximal PDC for activity sets whose cost and duration values fall within user defined ranges; and a sorted list display showing activity composition, PDC, cost, and duration for each selected activity set. The system interactively displays details of activities composing each activity set and the complementary cumulative distribution functions (CCDFs) corresponding to the selected activity set outcome. The database component of the system is built of more than 200 display panels, forms, tables, queries, reports, and macros.

In a database, numbers standing alone without annotation or explanation are without meaning to many, if not most, users. Yet most conventional uses of databases provide nothing more than numbers. This often means that the user may have to expend significant effort on finding documentation for the numbers provided in a database in order to adequately understand their meaning. To the extent that effort expended on finding explanations for the meaning of numbers in a database is effort that could be directed to using the numbers productively, the lack of explanation conveniently at hand while using the database represents an element of inefficiency.

Metadata

Within the visualizer display panel, titles, table column headings, table row labels, and graph legends are supported with metadata: information that defines, explains, and relates each of these data entities to WIPP, to the SPM-2 process, and to the scientific and engineering activities whose consideration produced the SPM-2 results. As a minimum, text provides brief definitions and explanations. These brief annotations are linked to a detailed online overview, which is internally hyper-linked to pop-up definitions, to related topics, and to a glossary often found in the system. Annotations are linked to the online electronic document library where detailed technical references for the WIPP project are provided.

In addition to the passive metadata, items of particular importance are supported by active-interactive panels. For example, one of the three principal display panels in the visualizer, the "Activity Set Composition Panel," is an interactive table. Its rows correspond to individual activity sets. It has two sets of columns. The first set of columns correspond to technical program areas and the second set correspond to the performance measures: PDC, cost, and duration. Clicking on a column heading activates a pop-up panel that displays a "passive" text definition of the technical program area associated with that column; this definition is hyper-linked to an appropriate destination in the

electronic document library. But if the activity set number that labels a row is clicked, an interactive panel is activated. This panel expands the corresponding row of the "Activity Set Composition Panel," displaying detailed information about every activity in the set. This panel computes and displays the PDC for any combination of outcomes for the set's component activities the user selects and upon the user's request will access the necessary data and generate the CCDF chart for the selected outcome combination. This interactive functionality allows the user to exercise one of the most conceptually elusive computations in the SPM-2 analytical process to gain a concrete grasp of the mechanics of the operation, providing an invaluable complement to the detailed explanation of the computation contained in the overview.

Both passive annotations and interactive panels are an integral part of the database structure along with the SPM-2 results. Every row, every column, every cell has an integrated information component which can be used for the appropriate level and detail of definition, explanation, or demonstration.

The Navigator

The navigator (Fig. 2), which acts as the user's portal to the system, provides point-and-click access to all of the other components of the system. The navigator is implemented using an off-the-shelf hyper-text/full text search system. Navigation to pre-defined points in the textual portions of the system is accomplished by HYPERLINKTM. Ad-hoc navigation is supported by a sophisticated full text search system that provides virtually instantaneous shift of focus to locations of topical interest in the text defined by the user. Topical interest can be formulated as words, phrases, and character strings (any of which may include fixed or variable length "wild cards" used to ignore irrelevant variations in textual expression of an idea of interest). These elemental topical recognition cues can be combined with both Boolean (and, or, not) and proximity (e.g., these two words within so many characters or so many words of each other) operators to express complex and precise search specification. The query formulation dialog is designed to be intuitive and easy to use.

Fig. 2

Search time is invariant with respect to query complexity and sub-linear by several orders with respect to the magnitude of text searched. This aspect of system performance is of importance quite beyond the dimension of mechanical efficiency. When pursuing an inquiry regarding the meaning of a particular data set, the more rapidly the system can respond, the more questions can be resolved within a unit of time.

The system provides a complete history of the user's trail through the text (whether by hyperjump or by topical search), displaying a list of all locations visited. The user can click on any item in the history and automatically return to that point in the text. A back-track function allows the user to retrace the trail one step at a time. These functions are an invaluable aide to understanding by allowing the user to leave a particular context to follow explanations and related information and then return with little effort to the original context armed with additional relevant information to augment understanding of the original context.

Online Context-Sensitive HELP

With over eighty hyper-linked topics, online context-sensitive HELP contains explanations of how to use the system, descriptions of each

display control (buttons, check boxes, etc.), and definitions of displayed data items. Brief definitions of SPM-2 terminology are also provided in the software HELP subsystem.

Many of the help panels are graphical and interactive. For example, a multi-level hyperlinked user structure diagram shows the relationships among the user interface panels. Clicking on a block in the structure diagram that represents a particular user interface panel hyperlinks to an image of the panel itself. The panel image, in turn is hyperlinked to explanations of the meaning of data displayed on the panel and instructions on how to use it.

Overview

Definitions of SPM-2 terminology as well as detailed descriptions of WIPP and the SPM-2 project and its objectives, methods, and computational procedures are contained in the SPM-2 Overview. This electronic document is internally hyper-linked, and hyper-linked to the database/visualizer system and to the electronic document library described below. The Overview is also full text content searchable.

Electronic Document Library

The fourth level of explanatory data, the electronic document library (EDL), is also internally hyper-linked and can be content accessed via full text search. The EDL contains the SPM-2 Final Report, the SPM-1 Final Report, the technical position papers which led to the computation of the data contained in the database/visualizer, a set of general references, and the full text for 40 CFR 191 and 40 CFR 268.6. The general references, which consist of SPM-2 charter documents and other key instructions establishing the scope and direction of SPM-2, are included as electronic page images (containing signatures, etc.) and as electronic text documents that can be full text searched.

EVOLUTION AND USES OF THE SPM-2 CD-ROM

The magnitude of the data and results suggested using a database to organize the results in a manageable form. A visualizer was included to enhance the value and utility of the data. The estimated size of the database suggested that a high capacity, high density storage medium would be needed. At about the same time as the storage medium became a consideration, DOE direction to make the SPM-2 data and results available to the public and the consequent need for distribution of many copies introduced the requirement for a low cost storage medium. The CD-ROM was the obvious choice. Release to the public also led to development of the navigator, metadata, and all of the other supporting information and tools that resulted in self-contained form of the final system.

Copies of the CD-ROM have been distributed to interested members of the public, WIPP participants, and the EPA. The system allows project members to understand parts of the project on which they had not participated. The supporting explanatory material in the system may be of interest to a wider audience than the results and data and may continue to be of value well after the original purpose of the system has been served.

CONCLUSIONS

The SPM performance-based decision methodology proved to be useful in structuring a large, complex decision and focusing attention on important portions of the problem.

A self-contained information system to support a specific task is made possible in part by the availability of information in electromagnetic form and by contemporary information system tools; like the personal computer, large capacity data storage media, fast processors, large ram

memory, low cost database management systems, HYPERTEXT and search engines, etc. The CD-ROM is a key element for distribution of self-contained information systems. The SPM-2 self-contained information system could not have been economically feasible as recently as three years ago. Just since the SPM-2 CD-ROM was released, there have been substantial improvements in all of the software and hardware elements used in its creation. Later this year CD-ROMs with a capacity of 6 gigabytes will be commercially available. A technology for manufacture of 100 gigabyte CD-ROMs is nearing maturity and is expected to be brought into manufacture within the next year or two. Multispectral approaches to recording and reading optical data are expected to yield CD-ROM systems with even higher capacities within the next five to ten years. The CD-ROM's cost performance is superior to any paper form or even any microform. When large numbers of copies are required, the per disk cost of the CD-ROM is small. The economies of distribution via CD-ROM are so compelling that there should be a conversion of many publication and record keeping requirements to this medium.

ASSURING PROPER PERFORMANCE OF THE WASTE ISOLATION PILOT PLANT BY USING ENGINEERED ALTERNATIVES*

Steve W. Wagner
WEC

James Maes
U.S. Department of Energy

CAO

ABSTRACT

The cost and benefit of continuous improvement: using Engineered Alternatives at the Waste Isolation Pilot Plant.

The Waste Isolation Pilot Plant (WIPP) faces many challenges in its bid to open as the nation's first Transuranic (TRU) nuclear waste repository. One of these challenges is to satisfy stakeholder's and regulator's concerns that the repository will perform as predicted, given the uncertainty associated with the long-term predictions of repository performance using a complex system of computer models. The Department of Energy (DOE) is committed to providing a safe and effective means of disposal for these TRU wastes. To provide assurance in the performance of the WIPP facility, the DOE has developed an Engineered Alternatives program.

An Engineered Alternative may take the form of a facility modification, a process modification, or waste form modification so as to address uncertainty which may be associated with important WIPP performance parameters (i.e. transport of radionuclides, increases in the mechanical strength of disposed wastes, the quantity of waste that would be released to the accessible environment in the event of a drilling intrusion). To aid in the evaluation of Engineered Alternatives, the DOE initiated the Engineered Alternatives Cost/Benefit Study in late 1994. The study examined potential alternatives and systematically screened them into a practical and technically feasible set. The study then examined this set of engineered alternatives for their benefits in addressing important WIPP performance-related uncertainty. Examples of the engineered alternatives that were examined include engineered backfills, plasma arc processing of wastes, supercompaction of wastes, repository configuration modifications, and combinations of these technologies. The study addressed the application of engineered alternatives to existing wastes, currently generated wastes, and wastes to be generated in the future. This report details the methodology employed to assess the impacts of each of these alternatives upon the entire DOE complex as well as the impacts on WIPP operations, and long-term repository performance.

In general, the DOE found that risks to workers and the general public are greater for complex treatment options than for simpler technologies such as engineered backfills. Every EA provides performance benefits and associated risks. The DOE must weigh these benefits and risks when making a final decision relative to EAs at the WIPP facility. This study will be used as a means to make this decision.

INTRODUCTION

The Waste Isolation Pilot Plant (WIPP) is a United States Department of Energy (DOE) pilot operation designed to demonstrate the safe disposal of Transuranic (TRU) waste in deep, bedded salt. The WIPP site is located in southeastern New Mexico. By law (U.S. Congress, 1992) the WIPP site has been withdrawn from public use to demonstrate the safe disposal of TRU waste. Also by law, disposal of TRU waste must comply with rules and regulations promulgated by the U.S. Environmental Protection Agency (EPA). The disposal system design consists of multiple barriers, both natural and man-made, located in a geologic salt deposit, 655 meters below ground. These barriers were selected because of their ability to permanently isolate the waste from the accessible environment and, at the same time, comply with performance and assurance requirements in subparts B of Title 40 Code of Federal Regulations Part 191 (40 CFR 191). This

regulation contains; 1) repository radionuclide containment requirements that must be demonstrated using a performance assessment and 2) specific assurance requirements used to provide additional confidence in the containment predictions. Engineered Alternatives (EAs) can be used to provide additional assurance measures beyond those used to meet the existing containment and assurance requirements. This paper uses the term EA to represent engineered barriers that are technically feasible processes, technologies, methods, repository designs, or waste form modifications which make a significant positive impact on the disposal system in terms of reducing uncertainty in performance calculations or improving long-term performance.

The DOE conducted a cost/benefit study to evaluate EAs for potential use as assurance measures. The purpose of this study is to provide the DOE with cost, benefit, and risk information for use in the selection or rejection of EAs. This study includes an assessment of estimated cost, potential risks, benefits, and relative repository performance impacts from the implementation of EAs, and where appropriate, the impact on the entire waste management complex (as a system) was considered. This study is entitled the Engineered Alternatives Cost/Benefit Study (EACBS).

The EACBS evaluated EAs using the following assumptions and guidance.

The present baseline design of the WIPP repository and its predicted performance meet the containment requirements of 40 CFR 191 without additional EAs. The baseline does not include waste processing above that required by the WIPP Waste Acceptance Criteria (WAC).

The results of the EACBS analysis are qualitative. However, both qualitative and quantitative methods were used to generate the output information.

The EA analysis used a multi-factor approach to evaluate the cost; the risk, both incidental and accidental; the benefit and schedule impacts that could be expected from the implementation of each individual EA. The factors were not ranked or weighted. The output of the EACBS compares the results of the EA analysis with the baseline and not to each other.

The approach used in the EACBS was to screen potential EAs compiled from previous studies, proposed regulations, and input elicited from stakeholders. The screening process used a working group composed of technical professionals from various fields to compare the proposed EAs to an EA definition and then to determine if those EAs that meet the definition also meet regulatory and technological feasibility criteria. The output of the screening process was a list of EAs that did not meet the definition and/or screening criteria along with the justification for their rejection from further study, and a list of EAs retained. This list of retained EAs was then optimized to determine which EAs would be analyzed further.

The screening processes evaluated 111 proposed EAs and screened them to a field of 54. The 54 EAs retained were optimized by the DOE using feasibility and effectiveness criteria to provide the final set of 18 EAs used in the EACBS. The 18 EAs remaining for evaluation consisted of nine basic alternatives and nine variations. The 18 final EAs and the baseline are briefly described below. (Numbers refer to their listing in the EACBS; they do not represent rankings or ratings.)

Baseline For EA comparison, the baseline is considered to be the current WIPP disposal system design. Waste meeting the WIPP WAC is emplaced in rooms that are approximately 4 meters high, 10 meters wide, and 91 meters long and access drifts in waste stacks of seven-pack drums (three high)

and Standard Waste Boxes (three high). No backfilling of the waste disposal area is included in the baseline case.

#1Supercompact Organics and Inorganics Solid organic and inorganic wastes are sorted to remove items that cannot be compacted. Sorted waste is pre-compacted in 132.6 liters (35-gallon) drums and then supercompacted. Usually, the contents of four supercompacted drums are placed in a 208-liter (55-gallon) drum. Sludges are not processed.

#6Shred and Compact Organics and Inorganics Solid organics and inorganics are shredded and compacted in 208-liter (55-gallon) drums using a mechanical shredder and a low pressure compactor. Sludges are not processed.

#10Plasma Processing of All Wastes All wastes are processed through a mechanical shredder and the input waste stream is controlled to ensure a suitable metal to non-metal ratio. The waste is processed through a Plasma Arc Centrifugal Treatment System and placed into 208-liter (55-gallon) drums.

#33Sand Plus Clay Backfill A mixture of medium grained sand and granulated clay is used as backfill. The mixture is placed around the waste stack and between the drums filling the void space between drums and unmined host salt in waste emplacement panels. A 50 percent void space is assumed.

#35aSalt Aggregate (Grout) Backfill A salt aggregate grout mixture is used as backfill to fill the void spaces between drums and unmined host salt in waste emplacement panels. This backfill consists of a cementitious-based salt aggregate grout with crushed salt aggregate and is pumped around the waste stack and between the drums filling the void spaces. A 20 percent void space is assumed.

#35bCementitious Grout Backfill A cementitious grout backfill consisting of ordinary Portland cement, sand and fresh water is pumped around the waste stack and between the drums filling the void space. A 20 percent void space is assumed.

#77aSupercompact Organics and Inorganics, Salt Aggregate/Grout Backfill, Monolayer of 2000 drums in a room that is 1.83 meters (6 feet) high, 10.06 meters (33 feet) wide, and 91.44 meters (300 feet) long Alternatives #1 and #35a are combined. The room height is lowered from 3.96 meters to 1.83 meters (13 feet to 6 feet) and only one layer of drums is emplaced in the room.

#77bSupercompact Organics and Inorganics, Clay-Based Backfill, Monolayer of 2000 drums in a room that is 1.83 meters (6 feet) high, 10.06 meters (33 feet) wide, and 91.44 meters (300 feet) long Alternatives #1 and #111 are combined. The room height is lowered from 3.96 meters to 1.83 meters (13 feet to 6 feet) and only one layer of drums is emplaced in the room.

#77cSupercompact Organics and Inorganics, Sand/Clay Backfill, Monolayer of 2000 drums in a room that is 1.83 meters (6 feet) high, 10.06 meters (33 feet) wide, and 91.44 meters (300 feet) long Alternatives #1 and #33 are combined. The room height is lowered from 3.96 meters to 1.83 meters (13 feet to 6 feet) and only one layer of drums is emplaced in the room.

#77dSupercompact Organics and Inorganics, CaO Backfill, Monolayer of 2000 drums in a room that is 1.83 meters (6 feet) high, 10.06 meters (33 feet) wide, and 91.44 meters (300 feet) long Alternatives #1 and #83 are combined. The room height is lowered from 3.96 meters to 1.83 meters (13 feet to 6 feet) and only one layer of drums is emplaced in the room.

#83Salt Backfill with CaO A backfill of commercially available granulated lime (also called quick lime which consists of CaO) and crushed salt are

placed around the waste stacks and between the drums filling the void space. A 50 percent void space is assumed.
#94aEnhanced Cement Sludges, Shred and Add Clay-Based Materials to Organics and Inorganics, No Backfill EA 94a includes two processes to treat the TRU waste. The first is an enhanced cementation process of previously solidified and "as generated" sludge. Existing sludges are fed into a mechanical crusher/shredder. The crushed waste is mixed with an enhanced cement and the product is poured into 208-liter (55-gallon) drums. Newly generated sludges are solidified with the enhanced cement. The second process shreds solid organic and inorganic wastes and adds clay to the shredded waste. This waste product is packaged in 208-liter (55-gallon) drums.
#94bEnhanced Cement Sludges, Shred, and Add Clay-Based Materials to Organics and Inorganics, Sand/Clay Backfill Alternative #94a and #33 are combined.
#94cEnhanced Cement Sludges, Shred and Add Clay-Based Materials to Organics and Inorganics, Cementitious Grout Backfill Alternative #94a and #35b are combined.
#94dEnhanced Cement Sludges, Shred and Add Clay-Based Materials to Organics and Inorganics, Salt Aggregate Grout Backfill Alternative #94a and #35a are combined.
#94eEnhanced Cement Sludges, Shred and Add Clay-Based Materials to Organics and Inorganics, Clay-Based Backfill Alternative #94a and #111 are combined.
#94fEnhanced Cement Sludges, Shred, and Add Clay-Based Materials to Organics and Inorganics, CaO/Salt Backfill Alternative #94a and #83 are combined.
#111Clay-Based Backfill Backfill consisting of commercially available pelletized clay is placed around the waste stack and between the drums, filling the void space. A 50 percent void space is assumed.
EACBS ANALYSIS FACTORS
The 18 EAs were analyzed with respect to the factors listed and described below:
1. The effects of EAs on long-term performance of the disposal system. This factor analyzes the EA's ability to limit water and radionuclide movement to the accessible environment and the potential consequences of human-initiated processes or events.
2. The increased or reduced uncertainty in compliance assessment.
3. The impact on public and worker exposure to radiation (at WIPP and off-site) both during and after the incorporation of an EA.
4. The increased ease or difficulty in future removal of the waste from the WIPP disposal system.
5. The increased or reduced risk (physical accidental, incidental and accidental chemical and radiation exposures) of transporting the waste to the WIPP.
6. The increased or reduced public confidence in the performance of the disposal system.
7. The increased or reduced total DOE waste management system cost and schedule impacts.
8. The impact on other waste disposal programs.
The following discussions outlines the analysis and results for each EA with respect to the eight factors.
Factor 1Effects of EAs on Long-Term Performance of the Disposal System
Factor 1 dealt with the impacts that an EA is predicted to have on the

long-term performance (not specific to the regulatory requirements) of the disposal system. Impacts were predicted using the Design Analysis Model (DAM), a computer model which considered the coupled processes of brine inflow, creep closure, gas generation, and radionuclide migration under undisturbed conditions. The consequences of three human intrusion scenarios were also considered. The three human intrusion scenarios postulated the existence of future boreholes that inadvertently penetrated the waste rooms and panels (waste horizon). These three scenarios were referred to in the EACBS as E1, E2, and E1E2. The E1 scenario involved a borehole that intersects the repository and a hypothetical pressurized brine pocket below the repository. The E2 scenario involved a borehole that only intersects the repository, and the E1E2 scenario involved one E1 and one E2 borehole that intersect the repository at different locations and times. This factor was evaluated by considering the impacts of each EA on the following:

Relative changes in the cumulative 10,000-year release of radionuclides based purely on the quantity of cuttings released to the surface from each of the three human intrusion scenarios

Relative changes in the cumulative 10,000-year release of radionuclides into the overlying Rustler Formation from each of the three human intrusion scenarios.

The impacts of each EA are expressed as changes in the parameters described above relative to the baseline, which is defined as unprocessed waste emplaced in disposal panels.

Although both disturbed and undisturbed conditions were simulated, the greatest consequences of releases are expected to occur as a result of human intrusion. Therefore, the study placed emphasis on the effects of EAs on mitigating releases from the human intrusion scenarios.

Factor 2The Increased or Reduced Uncertainty in Compliance Assessment Factor 2 estimated the EAs ability to treat uncertainty relative to the quantity of radioactive materials that are expected to be transported to the accessible environment as a direct result of human intrusion scenarios. This factor estimated the uncertainties by systematically manipulating the DAM input parameters from the Factor 1 analyses using a Monte Carlo simulation for each EA analyzed. The results of Factor 2 were then used in conjunction with those of Factor 1 to characterize the potential for an EA to provide additional assurance in the performance of the disposal system.

The treatment of uncertainty in compliance assessment can be realized by reducing both the magnitude of radioactive materials released to the accessible environment and characterizing the potential variability in that quantity. Factor 1 addressed the magnitude of this reduction through a Measure of Relative Effectiveness (MRE) for cuttings removal to the surface and groundwater transport to the Culebra Dolomite via the borehole, given scenarios E1, E2, or E1E2 occur. A MRE is a unitless factor that expresses the change in the magnitude of releases with respect to the baseline disposal system design. Factor 2 addressed the ability of the EAs to treat the uncertainty about these estimates of release quantity by treating the uncertainty about predictions of quantities of radioactive material that might be released as a result of the intrusion scenarios.

Factor 3The Impact on Public and Worker Exposure to Radiation Both During and After the Incorporation of an EA This factor characterized the human-health risks (incidental and accidental exposure) associated with the

implementation of an EA, including those impacts realized at the WIPP site and generator or disposal facilities that handle TRU or TRU-mixed waste. Potential impacts include radiation effects (both occupational exposures and the release of material resulting from an off-normal accident scenario), effects from the release of hazardous material, and, in the case of individuals within the facilities, ordinary industrial hazards. Impacts were considered for the following five groups of individuals at the WIPP and at the generator/disposal sites:

Workers directly involved with handling, processing, or storing TRU waste (generally referred to as "workers")

Other workers in the facility who are not directly involved with the TRU waste (referred to as "co-located workers")

The co-located worker who receives the highest exposure to radiation or hazardous material from TRU waste activities

Members of the public who live within 80.5 kilometers (50 miles) of the facility where the TRU waste is being handled, processed, or stored (generally referred to as "public")

The member of the public located off-site who receives the highest exposure from activities associated with TRU handling, processing, or disposal (often called the Maximum Off-Site Individual or MOI).

Factor 4The Increased Ease or Difficulty in Future Removal of the Waste from the WIPP Disposal System For the purpose of this report, waste removal is defined as the activity involving recovery of the waste after repository closure. In assessing the waste removal activities, the waste inventory and physical properties for each EA determine the underground panel geometry that would in turn determine the time required for underground removal (mining of the waste). Underground waste removal considered the compressive strength and density of the waste form as well as the consolidation of the backfill expected to occur after a specified period of time (if applicable). The occupational hazards for industrial accidents include the conventional hazards due to underground mining accidents, hazardous waste exposure, and radioactive waste exposure.

Factor 5The Increased or Reduced Risk of Transporting the Waste to the WIPP The transportation risk factor consisted of the human-health impacts due to radiation- and hazardous-material exposures that could potentially result from transporting CH- or RH-TRU waste. The risk factor was defined in terms of the radiological, chemical, and non-radiological/non-chemical impacts of either normal, incident-free transportation or transportation accidents. Because transportation does not impact all EAs; backfill only alternatives were not analyzed using this factor. The results broke down the total number of shipments from each storage/generator site and present the exposures to the public and workers. Where applicable, reported transportation risks and exposures are in the same units used in Factor 3.

Factor 6The Increased or Reduced Public Confidence in the Performance of the Disposal System This study was conducted in two phases to identify both historic and current public concerns about WIPP's post-closure performance. During Phase 1, existing public commentary was examined to identify concerns about post-closure WIPP. These comments and concerns were further analyzed to determine the relative frequency of the concerns and the persistence of concerns over time. Data sources included:

The WIPP FSEIS (DOE, 1990b)

Response to Comments for Amendments to 40 CFR Part 191, Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and TRU Radioactive Wastes (EPA, 1993)

Public Hearings on EPA's Proposed Rule 40 CFR Part 194, Criteria for the Certification and Determination of the WIPP's Compliance with Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level, and TRU Radioactive Wastes, March 21-24, 1995 (EPA, 1995)

During Phase 2, comments were collected during a series of focus group discussions and interviews in which participants were invited to share their concerns.

The combined findings from Phase 1 and Phase 2 analyses serve as considerations for selecting engineered alternatives that would address expressed public concerns. A qualitative assessment is made using the comment categories (comments were segregated based on the general nature of the concern) and determining which EAs address the concerns within these categories.

Factor 7The Increased or Reduced Total DOE Waste Management System Cost and Schedule Impacts Factor 7 analyzed increased or reduced cost and schedule impacts from implementation of EAs on the total DOE waste management system. The cost consists of summarized waste processing, transportation, backfill, and emplacement handling for the selected alternatives. The analyzed costs include a comparative analysis of the incremental change in cost of the alternatives relative to the repository baseline. This analysis estimated the level of funding necessary to implement an EA, the estimated manpower for the activities, and a conceptual schedule that provides start and stop dates for each EA analyzed. Cost was analyzed by developing process flow diagrams that segment the alternative into conceptual elements. The costs for the alternatives were developed on the basis of waste quantities and required throughput rates to meet the schedule constraints. The schedule analysis provides a measure of the time required to implement an EA relative to the baseline. The schedule included the incremental change of implementing an alternative on the baseline.

Factor 8The Impact on Other Waste Disposal Programs This factor included an assessment of the impacts that the EAs will have on other DOE waste processing and disposal programs, including programs for LLW and low-level mixed waste (LLMW). Major impacts were assessed based on the additional volumes of waste that were projected to be generated by TRU waste processing with respect to each EA.

Each EA can be classified in three categories, processing, backfill and combination alternatives. Processing alternatives modify the waste into a different chemical or physical matrix, backfill alternatives involve placing engineered materials around the unprocessed waste in the repository, and combination EAs which include combinations of processing, backfill, and repository design modifications.

The analysis considered three processing scenarios which differ based on where the processing was accomplished. Each processing EA was analyzed for regionalized, centralized, and decentralized processing scenarios. Regionalized processing, involved processed all of the waste at five of the major generator sites, centralized processing involved processing all of the waste at WIPP, and the decentralized processing scenario processed waste at the 10 major generator sites with all minor sites shipping their waste to the nearest major site.

OVERALL CONCLUSION OF THE EACBS

After a decision is made concerning the use of EAs at WIPP for additional assurance purposes, any subsequent selection of EAs will be made using total disposal system knowledge of the impacts related to the implementation of an EA. The EACBS report provides comparative information concerning cost, schedule, worker and public radiological/chemical and accidental/incidental risks, disposal system performance impacts, public perception, waste removal impacts, and the impact on other waste disposal systems. The process for the selection or rejection of EAs will use this and other related information to weigh the relative importance and to determine which EAs will be implemented. The information in this report will not be used as the sole bases for the selection/rejection of any individual EA.

The 18 alternatives were evaluated in the eight factor analysis yielding both qualitative and quantitative results. The analysis of each EA resulted in a large amount of data that necessitated the development of a more logical presentation of the results. The analysis results were compiled in a tabular summary and converted into quantifiable performance measures. Some factors were reported with one measure, while other factors could not be adequately expressed with a single measure. Table I summarizes the performance measures and units presented for each factor. A simplistic qualitative representation of the results was made from the performance measures comparing each alternatives performance with respect to the baseline repository design performance. Figure 1 summarizes this output information. As is the case for any analysis, these results are only as good as the models, data, and assumptions used in the analysis. These models, data, and assumptions are based on the best available current information. Technological understanding of many topics considered in this analysis is advancing rapidly, however, and it should be noted that changes in the modeling system or the model input, such as possible changes in our understanding of the future performance of specific EAs, could lead to somewhat different results. General observations are listed below.

The EAs can be separated into three general categories, Waste Processing, Backfill, and Combinations of these alternatives. The following observations were noted from the results of this analysis.

Waste Processing alternatives (EA # 1,6 & 10) were analyzed for the three processing scenarios (centralized, regionalized, and decentralized). Each scenario has inherent benefits and detriments. In general, processing alternatives impact the entire waste disposal system, involving the generator/storage sites, waste transportation, other waste disposal systems, and the WIPP waste handling system. Processing alternatives have higher cost, increased risks, and present increased schedule delays in comparison to baseline or backfill only EAs. In general, processing EAs have a marginal performance impact on the repository except for plasma processing (EA# 10) which shows a significant increase in repository impact, however, at the expense of the highest potential risk for all of the EAs analyzed.

Centralized ProcessingSince the centralized scenario processes all waste at one facility, the construction and operational costs are the lowest of the three waste processing scenarios. Operational and construction incidents and fatalities and public and worker chemical and radiological exposure risks are higher than the baseline. Transportation impacts are similar to the baseline. The centralized scenario has the highest

potential to impact system wide disposal operations. Since one facility processes all waste, this facility becomes a potential choke point for the entire system.
Regionalized ProcessingThe regionalized scenario processes waste at five generator/storage sites. The cost to implement regionalized EA scenarios are significantly higher than the centralized and slightly lower than the decentralized scenarios. In general, the worker and public radiological/chemical exposure risks are slightly higher than the centralized and lower than the decentralized scenarios. Transportation chemical exposure risks are slightly lower than the baseline since the waste is processed into a more inert matrix prior to shipment to WIPP. Accident and radiation risks are similar to the baseline.
Decentralized ProcessingFor this scenario, processing is performed at the ten major generator/storage sites. The scenario has the highest cost of the three processing scenarios (as much as $1 billion difference between the centralized and decentralized for EA# 77a-d). The operation/construction incidents and fatality rates are generally higher than both the centralized and regionalized (baseline included).

Backfill alternatives (EA# 33, 35a, 35b, 83 and 111) have the least impact on the entire waste disposal system. The WIPP waste handling system is impacted; waste transportation, generator/storage sites, and other waste disposal systems are not affected. Cost, schedule radiation and chemical exposure are similar to the baseline estimates. Backfill alternatives improve long-term disposal system performance.

Combination alternatives contain both multiple processing alternatives and/or backfill alternatives. These alternatives (EA# 77a through 77d and 94a through 94f) have benefits and detriments associated with each individual alternative type. The overall cost and schedule impacts are the highest of the EAs. Transportation, worker and public risks (radiological, chemical accidental and incidental) are also the highest of all EAs. The overall impact of combination EAs on long-term disposal system performance are comparable to that associated with the backfill and processing only alternatives.

PROJECTED TRANSURANIC WASTE LOADS REQUIRING TREATMENT, STORAGE, AND DISPOSAL*

K. Hong
T. Kotek
Argonne National Laboratory
Argonne, Illinois

ABSTRACT
Argonne National Laboratory's WASTE_MGMT computational model was used to calculate the volume of transuranic (TRU) waste loads requiring treatment, storage, and disposal at facilities located at various U.S. Department of Energy (DOE) sites. Inventory and generation data were taken from DOE's Waste Isolation Pilot Plant Transuranic Waste Baseline Inventory Report published in February 1995. Results indicate that WIPP's design capacity is sufficient for disposal of the contact-handled (CH) TRU waste located throughout the DOE Complex. Argonne compared the newly estimated waste loads with estimates from a previous study that used inventory and generation data published in 1992 and 1993. The differences

between the old and new estimates, expressed as a percentage of the newly estimated waste loads, range from a few percent to about 60% for treatment of CH TRU waste and from about 10% to 30% for its storage and disposal.

INTRODUCTION

Data on TRU waste loads are important input for validating existing capacities and determining the size and cost of new facilities for TRU waste treatment, storage, and disposal (TSD) for various siting configurations. Such data are used to assess transportation requirements and health risks to workers and the general public. Two of the key parameters for calculating TRU waste loads are the current inventory and estimated generation of TRU waste. A study by Hong et al. (1) projects waste loads estimated on the basis of inventory and generation data published in 1992 and 1993. Recently, updated inventory and generation data have been made available (2,3). This paper compares the waste load information calculated from the updated data with the information presented in the earlier study.

Before TRU can be disposed of at WIPP, it needs to be packaged or treated to meet various requirements. This study considers three levels of TRU waste treatment. The minimum level simply processes and packages TRU waste; it fulfills current WIPP waste acceptance criteria (WAC) requirements. The intermediate level reduces the gas generation rate of TRU waste after it has been disposed of in WIPP; it fulfills the requirements of the performance assessment study in addition to those of WIPP WAC. The most extensive level of treatment further destroys or stabilizes all hazardous constituents in TRU waste; it meets land disposal restrictions (LDRs).

This study considers three siting configurations for TRU waste treatment. In the regional configuration, TRU waste from individual sites would be sent to regional centers for treatment; in the decentralized configuration, it would be treated on the site where it was generated; in the centralized configuration, it would be sent from each of the sites to a centralized center for treatment. All treated TRU waste is temporarily stored in an interim storage facility before being shipped to WIPP for disposal.

UPDATED INVENTORY AND GENERATION DATA

The updated inventory and generation data are from revision 1 of the Waste Isolation Pilot Plant Transuranic Waste Baseline Inventory Report (WIPP-BIR) published in 1995 (2). These WIPP-BIR data are essentially the same as those provided in the Integrated Data Base (IDB) for 1994 (3). In general, these newly published data are more complete, consistent, and accurate than the data found in a previous study, which used data from the IDB for 1992 and from the interim mixed-waste inventory report published in 1993. The updated data were recently collected directly from each TRU waste generation or storage site. The latest data on the inventory volume of contact-handled (CH) TRU waste found throughout the DOE Complex is 73,000 m3; it was previously reported as 65,000 m3. The latest generation volume is 51,000 m3; the previously reported volume was 33,000 m3. Prediction of TRU waste volumes varies at each individual site.

The WIPP-BIR also provides detailed information on the characteristics of the TRU waste in each waste stream. On the basis of this information, waste streams were grouped into categories to facilitate their efficient treatment. The categories are aqueous liquid (1000), organic liquids

(2000), solid process residues (3000), soils (4000), debris (5000), special (6000), inherently hazardous (7000), and unknown (8000). The numbers in parentheses are abbreviated designations used in the accompanying tables and figure. TRU waste in each category would be treated in a specific treatment train that involves a series of treatment technologies including solidification, shredding, incineration, and packaging.

Figure 1 illustrates the treatment trains for five TRU waste stream categories being treated at a high level to meet LDRs. All treatment trains include a pretreatment step that segregates the waste into streams by separating liquids from solids or sorting out solids that have different physical properties. Currently, waste load calculations do not include three waste stream categories (special, inherently hazardous, and unknown). These three constitute less than 10% of total TRU waste volume and are assumed to be set aside to await special processing.

ESTIMATED WASTE LOADS

Argonne used the WASTE_MGMT computational model (4) to calculate TRU waste loads. Input consisted of the updated data from WIPP-BIR for technologies at each treatment site and for each siting configuration. WASTE_MGMT accepts three types of data as input: 1) the volume, mass, and contaminant characteristics of the waste stream inventory, by generating site and waste stream category; 2) TSD unit operating parameters; and 3) site configurations for treatment. Some TSD processes generate secondary output streams that are also tracked through the treatment process. For example, the primary output stream of incineration is ash, but a secondary stream of high-chloride salt waste is generated in the off-gas treatment of combustion gases (Fig. 1).

Fig. 1

Table I shows the annual CH TRU waste loads throughout the DOE Complex requiring representative treatment technologies for three siting configurations and three treatment levels: 1) decentralization of treatment to meet WIPP WAC requirements at each DOE site; 2) regionalization of treatment to reduce gas generation rates at five DOE sites; and 3) centralization of treatment to meet LDRs at one centralized DOE site. It also lists data on waste loads from the previous study for comparison. In general, the waste load for each technology under each siting configuration is higher when calculated with the updated data than when calculated with the previous data. The differences range from a few percent to about 60%.

Table I

Table II shows the total CH TRU waste loads throughout the DOE Complex for storage and disposal. The highest calculated waste loads for the disposal facility at WIPP are as follows: 1) about 140,000 m3 for the decentralization of treatment to meet WIPP WAC, 2) 93,000 m3 for the regionalization of treatment to reduce gas generation, and 3) 63,000 m3 for the centralization of treatment to meet LDRs. The differences between these data and the earlier study's data range from 10% to 30%. The estimated waste loads do not include waste volume that could result from environmental restoration activities. WIPP's design capacity for CH-TRU waste is 170,000 m3.

Table II

SUMMARY

This paper provides information on the volume of TRU waste loads requiring treatment, storage, and disposal at DOE facilities for three

siting configurations. Input consisted of updated inventory and generation data from WIPP-BIR. Results indicate that WIPP's design capacity is sufficient for the CH TRU waste found throughout the DOE Complex. In a comparison of waste loads estimated in this study with those estimated in a previous study, differences, expressed as a percentage of the newly estimated waste loads, ranged from a few percent to about 60% for treatment of CH TRUwaste and from about 10% to 30% for its storage and disposal.

CLEARANCE OF RADIOACTIVE WASTE: FRENCH AND BELGIAN APPROACHES IN RELATION TO INTERNATIONAL RECOMMENDATIONS

A. De Goeyse
L. Baekelandt
ONDRAF/NIRAS
Belgium
D. Jousselin
M. Jorda
ANDRA
France

ABSTRACT

During the last few years, important progress has been made at the international level with respect to the derivation of clearance levels for radioactive material. Although there is general agreement about the necessity to reach a broad consensus among the countries on this issue, it is important to note that these clearance levels must be supplemented by practical and industrial considerations, taking into account the prevailing situation in each country.

This paper focusses on two countries: France and Belgium in comparison with international recommendations.

For many years, France has been developing an important nuclear program to produce electricity. In this framework, radioactive waste management received almost immediate attention. A first low level waste surface disposal started operation in the "Manche" department, near La Hague, in 1969 and a second one in the "Aube" department, 200 km east of Paris four years ago. In 1991, French Parliament passed a law to define the way high level and long lived waste will be managed for the fifteen coming years. In 1994, French authorities decided to start studying, with the producers concerned, the way the very low-level waste, coming for example from the decommissioning of nuclear plants, could be disposed of.

The paper presents the framework of these studies and the first ideas of what could be dedicated disposal facilities.

As for Belgium, the legal role of ONDRAF, the national agency for the management of radioactive waste and enriched fissile materials, regarding clearance of radioactive material is explained. In accordance with the regulations, the objective of ONDRAF is to define practical rules for clearance of radioactive material in compliance with the general safety regulations. In order to reach that objective, a general strategy with well-defined steps is being implemented. To this end ONDRAF participated in advisory groups of the IAEA to recommend unconditional and conditional clearance levels, as well as in an EC working group on the clearance for recycling of metals. In addition, ONDRAF participated in two studies within the scope of a contract with the European Commission. The objective of these studies was to derive clearance levels for landfill disposal: the first study considered the case of an industrial landfill and the second one the case of a dedicated landfill for very low-level waste. The methodology and results of both studies are summarized and commented.

The present situation regarding clearance of radioactive waste takes into account the general Belgian regulations for radiological protection. To conclude, the Belgian and French approaches for clearance of radioactive material will be compared.

MANAGEMENT OF VERY LOW RADIOACTIVE WASTE IN FRANCE

The French approach to the management of very low-level radioactive waste should be placed in the larger context of waste in general, whether industrial, household or radioactive.

Waste in France

France generates approximately 600 million metric tons of waste per year. This is broken down into 400 million metric tons of agricultural waste, 102 million metric tons of inert industrial waste, 30 million metric tons of ordinary industrial waste, 15 million metric tons of special industrial waste, 3 million metric tons of toxic waste, 30 million tons of household waste, and 700,000 metric tons of hospital waste. Only 40,000 metric tons are radioactive waste.

Industrial and Household Waste

Ten years ago, France embarked upon a far-reaching program to improve non nuclear waste management and environmental protection. Regulations to reduce industrial and household waste volumes and to make their disposal sites safer have been set up in the past several years.

Three categories of landfills are distinguished. Class 3 landfills for inert industrial waste are not subject to regulation. Household waste and industrial garbage go to Class 2 landfills, for which a regulatory framework will be established by a ministerial order to be issued in the coming months. Special industrial waste goes to Class 1 landfills or burial sites with advanced safety systems, which are regulated according to the framework defined by ministerial orders dated December 18, 1992.

Nuclear Waste

France also developed a large-scale management program for radioactive waste commensurate with its nuclear power program, which generates 80 % of the country's electricity in 58 powerplants.

With the passage of the Waste Act on December 30, 1991, Andra, the National Radioactive Waste Management Agency, became a public service corporation with State oversight, independent of the CEA. The corporation's principal missions are:

- to design, construct and manage final disposal surface sites;

to register the location and condition of all radioactive waste on French territory; and

to study possible deep disposal facilities through a research program based on underground geological laboratories.

Radioactive waste is managed according to the specific activity and radioactive half-life of the waste. The following table indicates the disposal method to be used for each category of waste, based on the half-lives of the principal radionuclides present in the waste.

Table I

Short-lived low- and medium-level waste is disposed of at the Centre de l'Aube disposal site 200 kilometers east of Paris, near the city of Troyes. This site receives 20,000 m3 of waste per year; the total site capacity is 1,000,000 m3. The site was opened in 1992 and it should be able to receive low- and medium-level waste for the next fifty years.

Concerning high-level waste and long-lived medium-level waste and, in accordance with the Waste Act, Andra is charged with the creation of two underground laboratories designed to certify the suitability of the site to host a repository which provides adequate radioactive confinement and to verify the feasibility of the proposed repository design. This is to be demonstrated by the year 2006. In the event of a favorable outcome at that date, a repository could be operational in 2020. The Waste Act also requires the pursuit of two other programs in parallel: separation and transmutation of long-lived emitters in the waste, and enhanced conditioning and long-term storage.

Long-lived low-level waste will be disposed of in near surface disposal facility currently under design which should be operational by 2001.

Radioactive waste disposal sites, regardless of the activity of the waste (low-, medium- or high-level), are managed according to special regulations for licensed nuclear facilities, including nuclear reactors, reprocessing plants, and radioactive waste disposal facilities. These facilities are subject to special regulations based on a December 11, 1963 decree. The technical requirements are dictated by the Fundamental Safety Rules. The regulatory authority in charge of regulating these licensed nuclear facilities is the Department of Nuclear Facility Safety, known as the DSIN, which reports to the Ministry of Industry and to the Ministry of the Environment.

Very Low-level Waste

Our inventory would not be complete without mentioning very low-level waste. In principle, the June 20, 1966 decree constitutes regulations currently applicable to this type of waste. This decree considers materials whose activity levels are less than 100 Bq/g (or 500 Bq/g for solid natural materials) to be "non radioactive" and thus excludes them from the "radioactive" waste category. Although this exclusion should allow such waste to be disposed of as ordinary waste, this approach is not well received by the public. It is also recognized that the decree on radiation safety was not written to define categories of radioactive waste. For this reason, based on several reports commissioned by the Government in the last five years, restrictive practices have gradually been set up for waste whose activity levels are from 1 to 100 Bq/g (or 500 Bq/g in the case of solid natural materials). At the same time, monitoring gantries were installed at the entrances to disposal sites and scrap recycling sites. These gantries have detected a not insignificant number of radioactive anomalies, thus confirming the need to specify rules for the management of this type of waste.

The DSIN, together with ANDRA and the operators, followed the recommendations of the government reports by declaring that very low-level waste should not be treated as ordinary waste, even for activity levels of below 100 Bq/g, and should not be mixed with other waste. This waste should be disposed of at a special site with the same level of safety as the other nuclear facilities. The disposal site would be turned over to ANDRA, in accordance with the Waste Act, for long-term management and monitoring, i.e., approximately 100 years.

In the view of the DSIN, one fact is clear: government imposition of universal thresholds below which certain waste could be treated as ordinary, or "non-radioactive", waste is precluded for a variety of reasons:

- the public is not ready for the establishment of such universal "below regulatory concern" thresholds, and would perceive such a decision as self-serving and designed to allow the generators to get rid of their waste;
- thresholds could create an incentive to dilute the waste by mixing non radioactive waste with other, very low-level waste to bring its specific activity to below the regulatory threshold; and
- it is not presently feasible to reliably monitor large quantities of waste and on a large-scale when it leaves nuclear facilities or enters a disposal site, and this difficulty will only increase as the first light water reactors are dismantled, generating large volumes of concrete.

A management system should therefore be set up specifically for very low-level waste which distinguishes between the potential sources of such waste, whether the source be the "conventional nuclear sector" of the "miscellaneous nuclear sector". The first sector includes the nuclear power and defense industries; the second sector includes other industries, such as the chemical and metallurgical industries (phosphates, rare earths, etc.), which handle very low-level materials, sometimes without realizing it.

For the "conventional nuclear sector", the French regulatory authority looks for clear-cut, safe and responsible management of very low-level waste based on two principles:

- user responsibility for the fate of the materials used; and
- detailed identification of materials that may be contaminated by radioactive materials, from the initial contact to the moment they leave the site ("traceability").

In practical terms, adhering to these principles requires:

- the division of facilities into areas which are likely to generate radioactive waste and areas with no radioactivity;
- waste research;
- approved and monitored treatment processes;
- dedicated disposal sites managed by ANDRA; and
- more stringent regulatory control.

For the "miscellaneous nuclear sector" the principles should be the same. However, the number of players involved and their lack of knowledge about radioactivity make it necessary to check for radioactivity in their materials with a monitoring gantry at the entrance to disposal sites, steel plants, scrap recycles, or other facilities. If radioactivity is detected that is significantly higher than background radiation, the Regional Divisions of Industry, Research and the Environment could intervene and, based on an analysis of the specific cause, find the

material to be "radioactive waste". ANDRA would then take charge of the materials found to have very low activity levels.

BELGIAN SITUATION AND PROSPECTS FOR CLEARANCE OF RADIOACTIVE WASTE

Radioactive waste in Belgium is managed by ONDRAF-NIRAS, the national agency for radioactive waste and enriched fissile materials created by a law of March 1981 amended in October 1991. The competencies of ONDRAF include transport, conditioning, temporary storage and final disposal of radioactive waste, as well as the various related quality control and quality measures such as the definition of waste acceptance criteria and the qualification of waste treatment facilities.

As for the clearance of radioactive waste, ONDRAF-NIRAS was charged by law with the tasks of establishing, on the basis of general rules proposed to and approved by the competent authorities, detailed specifications and practices regarding clearance of radioactive waste, hereafter called clearance rules. The competent authorities are the Radiological Protection Office of the Federal Ministry of Public Health and Environment and the Office for the technical safety of nuclear installations of the Federal Ministry of Employment and Labor. In a very short future both offices will be replaced by a single federal agency for nuclear safety under the Ministry of Internal affairs.

In order to fulfill its task of establishing acceptance rules and criteria for clearance, ONDRAF has defined a global strategy which is detailed below.

Awaiting the definition of clearance rules and agreement on these rules, the Belgian regulations on radiological protection remain valid. These regulations stipulate that waste generated by licensed facilities must be treated as radioactive waste when its radiation exceeds the natural background level. It is one of the responsibilities of the health physics department of the facility to verify the radiation level. This means in practice that clearance of radioactive waste has been performed until now on a case by case basis and in a non coherent way.

General Strategy for Setting Clearance Rules

In accordance with the regulations, the objective of ONDRAF-NIRAS is to define practical rules for clearance of radioactive waste in compliance with the general safety regulations. These rules will be particularly important in the case of dismantling and decommissioning of nuclear facilities or after large repairs. These operations generate large quantities of low-level or slightly contaminated material which are suitable for processing to reach very low residual activity levels and for clearance. The clearance rules will have an impact on the development of decommissioning sequences and on the evaluation of their costs.

The clearance rules will include clearance levels but also control measures related to these clearance levels. The clearance levels will make it possible to define, for both unconditional and conditional clearance, acceptable levels for surface contamination and for the activity concentrations of groups of isotopes depending on their radiotoxicity. The derivation of unconditional clearance levels must necessarily take into account radiation exposure during all of the reasonably possible uses and movements of the materials intended for clearance. For a given radionuclide, the derived clearance level will be determined by the scenario and exposure pathway which give rise to the highest radiation dose. When a practice that is suitable for clearance is well defined, e.g. landfill disposal, it will usually be possible to take account of the known features of the practice. These considerations may

be expected, in general, to lead to higher clearance levels as compared to the unconditional levels. Furthermore, in case of conditional clearance, the clearance rules must also make it possible to define rules concerning the system and measures to be implemented in order to make sure that the cleared material follow the selected route.

The second aspect of the clearance rules concerns the control of the clearance levels. It is indeed important from a regulatory viewpoint, to be able to verify the applicable clearance levels. This can be done by direct measurement on the material to be cleared, by laboratory measurements on representative samples, by use of properly defined scaling factors or by other means accepted by the competent authorities. Of course, the choice of measurement strategy and appropriate instruments will depend on the type of material and radionuclides present.

ONDRAF-NIRAS has defined the following strategy to set the clearance rules:

The different actions must take into account the international state of the art and progress. It should indeed be kept in mind that materials cleared in one country are not distinguishable from non-radioactive material and may be moved from one country to another. It is therefore necessary to develop an approach and to derive clearance levels that are agreed upon internationally. To this end ONDRAF-NIRAS participated actively in advisory groups of the IAEA (International Atomic Energy Agency, Vienna) set up to derive and recommend unconditional and conditional clearance levels for solid materials containing radionuclides, as well as in a working group of the European Community, set up to derive clearance levels for recycling of metals.

On the basis of conservative nuclear safety rules, in particular for the individual dose criteria, clearance rules will be defined for the following practices:

- recycling or re-use in the nuclear sector;
- recycling or re-use in the non-nuclear sector;
- disposal in an industrial landfill or in a specific landfill intended only for cleared radioactive material (so-called dedicated landfill). The choice between the two types of landfill is first of all an economic choice strongly linked to the quantity of material likely to be cleared. For the derivation of clearance levels for landfill disposal, two specific studies were performed which are detailed hereafter.

In addition to these conditional clearance levels, levels for unconditional clearance will be proposed.

The clearance rules, including practical measures such as controls, will be presented and discussed with the main producers of radioactive waste. It should indeed be noted that one objective of the clearance rules is to ensure coherence of these practical measures between the various waste producers.

After reaching a consensus with the waste producers, the clearance rules will be presented to the competent authorities before becoming effective.

Clearance levels for Landfill Disposal

Within the framework of a contract with the EC (European Commission), ONDRAF participated in two studies to derive clearance levels for landfill disposal: the first concerns the case of an industrial landfill and the second the case of a dedicated landfill for very low radioactive waste.

a. Clearance levels for industrial landfill disposal

Following a conservative approach, the following masses of very low-level radioactive waste were assumed: 100,000 ton averaged over a period of 30 years sent to one class 1 landfill (industrial waste) or ten different class 3 landfills (inert waste).
As a landfill disposal site accepts waste from different origins, it was assumed that the very low-level waste is mixed with ordinary industrial waste.
Different exposures were selected: engine driver, foreman, truck driver, general public.
In addition, the water pathway was studied on the basis of data for a specific class 1 landfill.
The results and a comparison with the (IAEA) unconditional clearance levels are given in Table I.
The table shows that the derived levels vary between several orders of magnitude:

- from 1 to 800,000 Bq/g for the class 1 landfill;
- from 1 to 2,000,000 Bq/g for the class 3 landfill;

They reflect the highly different radiological characteristics of the radionuclides. The lowest values are found for the radionuclides with high gamma energy and for the alpha emitters.
The water pathway was found not to be limiting.
The dose to the truck driver appears to be the limiting scenario for many radionuclides (for this scenario no mixing with other non-radioactive waste is assumed).

b. Radiological impact of a special landfill site for very low radioactive waste

This study was aimed at evaluating the exposure, in terms of doses, resulting from the operation (for workers) of a special landfill (with hypothetical geology and technical characteristics) filled exclusively with very low radioactive waste.
As in the first study, the impact of the site on the public during the post-closure phase was taken into consideration.
The activity of the waste likely to be sent to the facility ranges from 1 to 100 Bq/g.
In the absence of actual data on the isotopic composition of the waste involved (as for the first study: 100,000 tons over 30 years), the radiological impact was based on a specific uniform activity of 100 Bq/g.
For the workers, the highest doses are logically obtained for the radionuclides with high gamma energy and for the alpha emitters, but remain limited to values around 0.01 mSv/year.
For the individuals of the general public, doses around 0.1 mSv/year are obtained for the alpha emitters, and for some radionuclides such as Nb-94, Ag-108 m and Ra-226 doses above 1 mSv/year are found.
The water pathway generates the highest dose for I-129 (around 0.1 mSv/year); the other doses remain below 0.02 mSv/year.

CONCLUSION

Both in France and in Belgium, management of very low-level waste fits within the scope of the general policy on radioactive waste management pursued by the respective national organizations, i.e. ANDRA for France and ONDRAF for Belgium. The management strategy outlined by these organizations shows nevertheless different levels of progress in the two countries.
In France, a strategy was outlined in consultation with the safety authorities for very low-level waste, i.e. waste with an activity below

100 Bq/g produced by the "conventional nuclear" sector. This strategy aims at disposing of the waste in a "dedicated" disposal site after having identified the areas of installations that are likely to generate radioactive waste.
In Belgium, the strategy outlined by ONDRAF aims at defining exemption levels and rules for different practices according to the nature of the waste and its destination. One of the practices envisaged corresponds with that foreseen in France. However, this solution of "dedicated" disposal can only be envisaged, both technically and economically, for waste quantities. It is also not excluded that, for some type of very low active waste, a so called unconditional clearance, based on internationally agreed levels, will be possible in Belgium after agreement of the competent authorities.
The different progress in the implementation of a strategy for very low-level waste in the two countries can be explained, among others, by the different order of priorities due to the existing quantities of waste suitable for disposal.
It should be noted that both organizations agree on the fact that one of the main difficulties associated with the management of this category of waste is caused by measurement problems (levels, representativity of samples) regarding low activity levels.

ABSTRACT
OHM Remediation Services Corp., Nuclear Services Division (OHM) has developed a container that is capable of holding high activity waste and can be shipped as a DOT Type A shipment. By making the container special form the amount of activity that can be transported in a Type A shipment is greatly enhanced. This leads to a great savings in the transportation costs associated with cask rental, handling and shipping. Normal form packages can allow access to the radioactive material without destruction of the package. Special form material presents an extra degree of protection to the environment by requiring the package to be destroyed to get access to the radioactive material. The package must undergo specific testing requirements to meet these criteria (10 CFR 20 and 49 CFR 173). Typically, sealed sources do not meet the requirements for normal form. For example, Radium 226 is normally limited to 50 milli-curies per container for transportation as DOT Type A. With the special form container up to 10 curies of Ra 226 can be transported in a single package.
DESCRIPTION OF WORK
OHM was performing a superfund remediation job for the EPA in Queens, New York which involved the removal of approximately 120 curies of radium needles, plaques and sources, plus various amounts of highly contaminated material. The problem arose as to how to dispose of the sources in an efficient manner to minimize radiation exposure, without escalating

costs. The following items were taken into consideration that lead to the development of the special form disposal container:

Prevent having to handle each of the approximately 10,000 sources,
Limit whole body and extremity exposure,
Not having to determine if they leaked or not, and
Prevent an excessive number of shipments of small activity,

As mentioned before, with radium the packaging efficiencies greatly increase with the special form container. Other radionuclides where this container offers a distinct advantage are given in Table I.

Table I

Through review of all of the restricting criteria from the disposal site and the Department of Transportation, a plan of action was made to develop several operational containers capable of meeting the above needs. Criteria considered included:

A. Exposure limits on the package - 1000 mR/hr.
B. Exposure limits on the surface of the vehicle -200 mR/hr.
C. Exposure limit of 10 mR/hr at 2 meters from the vehicle.
D. No leaking sources are acceptable for disposal (over 10,000 sources had to be determined to be either leaking or non leaking).
E. Sources required to be inside a DOT 2-R container.
F. The disposal site can have no more than 25 curies above ground at one time.
G. Weight constraints on the 55 gallon drum (1400 lbs).

Immediately, the concern turned to protection of the workers loading and handling the container. Through calculations and shielding analysis, the exposure rates for various amounts of radium were approximated on the outside of the container. Appropriate shielding was then designed to protect the workers loading the container, welding and inspecting the container, and then handling the container for shipment. Calculations showed unshielded radiation levels on the outside of the container to be approximately 15 R/hr on contact on the side, 21 R/hr on contact on the bottom, and 800 mR/hr at one meter from the side of the container.

The use of lead shielding was obviously necessary to allow the workers to stay within the administrative dose guidelines of OHM Nuclear to meet its ALARA philosophy. Calculations were then done to determine the maximum amount of lead that could be placed in a container and still meet the weight constraints of our 55 gallon drum and the testing criteria of 49 CFR 173.

INNER CONTAINER

The size of the inner, special form, container was determined by considering what type of material would be placed inside. Radium sources can be used for pharyngeal applications that require needles up to eight inches in length, with the diameter being about one eighth of an inch. Other longer needles were assumed to be possible, but the probability was determined to be low and it was decided they could be remotely handled and made to fit the container. The potential for extremely high dose rates that are associated with 10 curies of radium 226 (or 30 curies of cesium 137) warranted special shielding considerations. With the burial site criteria of radium being required to be inside a DOT 2-R container the diameter of the encapsulating container and additional lead shielding was limited to 12" by the DOT specifications for the 2-R container. Therefore, the next consideration was a compromise between the physical sizes of the inner, special form, container and the lead shielding that would reduce the exposure rates the most for this application. Because of

the constraints of welding and testing the weld on the special form container extra attention was given to the exposure levels at the top of the inner container. The dilemma here arose from the fact that the top had to be welded, and then the weld inspected, both tasks requiring close hands-on work in a high radiation field. See Fig. 1. Steel was used as shielding material on the sides of the container, while lead was used at the top. To meet special form criteria the outer sides, top, bottom, and lifting lugs were all stainless steel. All welds were inspected non-intrusively prior to final release.

Fig. 1

ENCAPSULATED CONTAINER

The special form container was required to be placed inside a DOT 2-R container, which limited the physical size to a 12 inch diameter. Additional shielding was required to maximize the activity for disposal in the inner container. With the evaluation of the weight limitations, the size dimensions, the shielding needs, and possible materials, it was determined that one inch of lead was the maximum that could be placed along the sides of the encapsulating container. The bottom would require more shielding because of its close proximity to the sources and could have one and one half inches of lead shielding.

Fig. 2

It was determined that shielding inside the special form container was required to meet the needed constraints, mainly due to ALARA considerations. Testing of the special form container proved difficult because of the weight involved with a container of such size. The walls of the container were made from one quarter inch stainless steel. Therefore, the welding to seal the bolt of the container had to be a Tungsten-Inert Gas (TIG) weld. This type of weld is difficult and was made even harder by being in a difficult place to perform. As can be seen it would be inside 55 gallon drum, inside a shielded 2-R container.

In the development of the container several designs were proposed and tested. Physical constraints that were imposed by the mere numbers of sources to be handled and the uncertainty of the dimensions of the items to be disposed required shielding analysis of all proposed containers as part of the design phase. Changes that were the result of actions at the superfund site required an additional container be constructed with a wide mouth opening. This container was capable of holding items too large to fit inside the small opening of the first container. The larger container was also designed to completely enclose the smaller container if the need arose.

CONCLUSION

The containers designed were capable of meeting the design criteria as imposed by DOT and the burial site and were used extensively throughout this project and at other projects. The dose received by individuals handling the large amounts of radium fell well within the ALARA concept. It was shown that high activity waste could be handled safely and efficiently in large quantities without exposing the worker to undue risk. In one instance over two curies of radium was packaged and shipped for disposal with the exposure for all workers involved totaling 0.49mSv (49 mrem).

GETTING STARTED AND MAKING PROGRESS

ABSTRACT

This paper reports on the current efforts of the Office of Spent Fuel Management (EM-67) to meet the major challenge facing the U.S. Department of Energy-owned spent fuel Quality Assurance community: the implementation of an effective, efficient, and integrated Quality Assurance program that meets all regulatory requirements of the Office of Civilian Radioactive Waste Management's Quality Assurance Requirements and Description (DOE/RW-0333P). The paper presents the goals and status of the implementation of the Department's Spent Fuel Quality Assurance Program. It summarizes progress made in assessing and implementing Quality Assurance requirements for Department-owned spent fuel, the methodology for verifying compliance, where appropriate, with DOE/RW-0333P, and implementing processes and procedures to qualify Quality Assurance programs and verify quality affecting data. Lastly, it discusses the vision forward initiatives for the Spent Fuel Quality Assurance Program.

INTRODUCTION

The Department of Energy (DOE) confronts the difficult task of managing and disposing of the inventory of DOE-owned spent nuclear fuel (SNF) generated by past production and ongoing test/research reactor operations. In 1992, the Secretary of Energy directed the Assistant Secretary for the Office of Environmental Management (EM) to develop an integrated, long-term SNF management program to consolidate, under EM management, all DOE SNF and associated facilities not addressed by the Office of Civilian Radioactive Waste Management (RW), which manages the program for the safe disposal of SNF produced by civilian nuclear power reactors. Currently, EM is responsible for the DOE-owned SNF Program's policy, while overall coordination is assigned to the Office of Spent Fuel Management (EM-67). EM-67 is therefore responsible for mitigating vulnerabilities and implementing the safe and cost effective near-term interim storage of DOE-owned SNF prior to the final disposition of the fuel at an RW-managed storage facility or repository.

An integral component of this responsibility is the implementation of quality assurance (QA) programs for the management of DOE-owned SNF (1). QA includes all those planned and systematic activities necessary to provide confidence that a structure, system, or component will perform satisfactorily in service. Commonly required actions in a QA Program include well-defined responsibilities and authority, controlled and documented personnel qualifications, and documented evaluation activities. QA assists in ensuring that the SNF Program is managed in a coordinated manner consistent with relevant technical requirements. A systems engineering process was introduced to the Program to establish a consistent complex-wide standard of excellence which fosters continuous improvement and enhancement of SNF activities. This process was intended to facilitate the application of appropriate QA practices and applicable standards integrated into the SNF management system of planning program,

establishing requirements, integrating activities, and providing resources throughout the life cycle of the SNF Program, from assuring existing storage to preparing for final disposition.

A key element of the SNF QA Program is its linkage with the RW QA Program. A primary element of RW's mission is to site, construct, and operate a geologic repository for the disposition of commercial nuclear power plant spent fuel and high-level waste (HLW). Since the Department of Energy has determined that the path forward for final disposition of its spent fuel is in the geologic repository, EM-67 has adopted RW's Quality Assurance Requirements and Description (DOE/RW-0333P, hereinafter referred to as the QARD) as the baseline for all quality affecting activities associated with preparation for disposal (2).

Because DOE-owned SNF may eventually be turned over to RW, it must be characterized and processed so as to meet the long-term Nuclear Regulatory Commission (NRC) requirements for long-term disposal and thereby be acceptable to RW at the time of turnover (3,4). All producers of HLW and owners of SNF are required to comply with these QA requirements to assure the acceptability of their HLW and SNF by RW for disposal in a geologic repository. The QARD, the principal QA document for RW, establishes the requirements for the HLW/SNF QA program. It is a compliance-based document designed to meet the NRC licensing requirements. Since the QARD has been reviewed and approved by the NRC, its adoption will facilitate the movement of the SNF Program toward NRC-licensed (or licensable) interim storage facilities. Additionally, EM adoption of the QARD will align the SNF QA programs with the RW QA program and facilitate ultimate disposal. Implementation of the QARD involves EM-30, EM-60, DOE Operations/Area Offices, and its management and operating (M&O) contractors (5).

The major challenge facing the DOE-owned SNF QA community is the implementation of an effective, integrated, and efficient QA program that meets all regulatory requirements of the QARD. The goal of the DOE-owned SNF QA Program is to obtain RW acceptance of the National SNF QA Program and begin qualification of SNF sites to support the SNF Program's path forward for final disposition. The systems engineering breakdown provides the road map to implement the QARD and other applicable standards.

BACKGROUND

The SNF Program is currently incorporating the RW QA requirements to SNF quality-affecting activities. Since EM-30 initially established a QA program for HLW vitrification activities that addressed all RW QARD requirements, the Deputy Assistant Secretary for Waste Management (DASWM) concluded that the HLW QA program should be extended to include SNF. Because the HLW QA Program was accepted by RW on August 13, 1994, the Office of Program Integration (EM-33) and the Office of Spent Fuel Management (EM-37) signed an agreement in principle (AIP) and a proposed implementation process to designate the HLW/SNF QAPM (EM-33) as the single point of contact between EM-30 and RW for QA matters, and to develop one set of SPPs for SNF and HLW for implementation of the requirements in the QARD (6). In August 1994, a working group of EM-33 and EM-37 HQ and site personnel was established to integrate applicable SNF QA activities into the HLW SPPs. The SPPs describe internal and external interfaces, organizational structures, requirements and responsibilities for the HLW and SNF quality affecting work at Headquarters. Compliance with the SPPs is mandatory for all HQ

organizations (including HQ support offices) involved in the HLW/SNF QA Program.

The HLW/SNF SPPs were issued in February 1995. In addition, the HLW/SNF Quality Management Plan (QMP) was developed as an appendix to the HLW/SNF SPPs. The QMP describes the HLW/SNF QA Program and the SPP process for controlling HQ and HQ support offices. The QMP provides the overall basis for an effective QA program to address both the HLW and SNF functions and corresponds to the criteria of the QARD. It identifies the applicability and responsibilities for the appropriate programmatic requirements for HLW/SNF QA activities, including a general description of the QA program hierarchy, identifying those elements applicable to HQ and guidance information at the Operations Offices and M&O contractor levels. The QMP is based on the requirements of EM-30, "Quality Assurance Program Description" (QAPD), and the QARD. Also under this AIP, EM is developing for submission to RW an SNF requirements matrix that identifies the SPPs to implement the QARD requirements.

In December 1995, the Office of Spent Fuel Management (EM-37) was realigned under the Office of Nuclear Material and Facility Stabilization (EM-60). This realignment/reorganization shifted program management functions within the following EM Offices:

The Office of Spent Fuel Management (formerly EM-37) has become EM-67, interfacing with other EM-60 offices (EM-63 and EM-65) on SNF site issues;

HLW/SNF QAPM (formerly within EM-33) is now in EM-37 (Office of Technical Services) and is still charged with overall management of HLW/SNF QA Program;

QAPM is still the lead point-of-contact to date between RW and EM for QA activities related to both HLW and SNF; and

QAPM is responsible for submitting QA documents to RW for acceptance, i.e., organizational descriptions and QARD Requirements Matrices, as required by RW QARD).

Figure 1 displays the document hierarchy chart for the SNF Program.

Fig 1

RW ACCEPTANCE OF THE HEADQUARTERS SNF QA PROGRAM

The QA Program being applied to the DOE-owned SNF activities is described in the HLW/SNF and the SPPs. The SNF Program has established the QARD as the standard for the following applications:

Characterization or data collection for input or use for interim storage or ultimate disposition that could affect the acceptance of SNF in a Nuclear Regulatory Commission (NRC) licensed storage facility or repository.

Conditioning for interim storage or into final form for disposal that could affect the acceptance of SNF in an NRC licensed storage facility or repository.

Handling and packaging for interim storage or disposal that could affect the acceptance of SNF in an NRC licensed storage facility or repository.

The implementation of the QARD for these activities will facilitate the interfaces between EM, RW, and NRC and assure the smooth transition of the SNF from existing conditions through interim storage to final disposition.

The appropriate criteria from other quality standards will be utilized as they apply to the remainder of SNF activities as defined in the individual site quality program. If the decision is made to privatize the

operations of new interim storage facilities or packaging and transportation of SNF, the NRC regulations will apply through the direct application of Title 10 of the Code of Federal Regulations (CFR), Part 72 or Part 71, respectively, assuming privatized storage facilities will be licensed by and appropriate fees paid to the NRC.

The Headquarters SNF QA Program is taking a number of actions to obtain RW acceptance by March 29, 1996. Figure 2 displays the implementation of the SNF QA Program. Actions or steps taken or to be taken include:

Coordinating with RW in revising the QARD to include an SNF QA Appendix.

Revising the QMP, which defines the scope of application to those SNF Program management activities performed within EM-60 organizations involved with the SNF Program. The QMP identifies the specific authority and responsibility for SNF quality-related activities, and also defines roles, responsibilities, and activities of the EM-30 organization assigned QA responsibilities for the SNF Program.

Revising the SPPs to show compliance with recent revision of the QARD. Issuing the SPPs to SNF personnel. Providing SPP training to all SNF personnel who implement SPPs.

Performing internal reviews of implementation

Submitting RW requirements matrix and organization procedure to RW for acceptance

Performing evaluation and assessment activities of implementation both at HQ and in the field

Obtaining RW-3 acceptance of the SNF QA Program

Fig 2

SNF QA PROGRAMS AT THE SITES

Documents from a variety of sources are used to develop the quality program, quality assurance plans, and procedures to control SNF work activities. However, the contents of the source documents do not necessarily apply to all program activities. The applicability of quality program regulations, DOE Orders and directives, national standards, and guidance documents to the SNF program needs to be evaluated on a site-by-site basis in accordance with the following guidance. For each specific site, the quality assurance programs for SNF management are still under development. Exceptions and/or changes to each site's quality assurance program may be needed to demonstrate implementation of the QARD.

In response to DOE Order 5700.6C, Quality Assurance, and 10 CFR 830.120, Quality Assurance Requirements, each site is developing or has developed a QAPD to cover their site operations. These QAPDs establish the foundation for operation of each site's quality assurance program. The QAPD applies to organizations, individuals, vendors, and other entities working for the site. 10 CFR 830.120 provides requirements for M&O contractors in the design, construction, and operation of nuclear facilities, while nonnuclear facilities are governed by DOE Order 5700.6C. The 5700.6C requirements are applicable to site activities not related to SNF activities.The SNF Program is undertaking actions to qualify the SNF QA Programs at Idaho, Richland, and Savannah River by FY 1996 and FY1997. (See Fig. 3). Actions or steps include:

Directing (via the EM Program Execution Guidance for FY 1996) RW QARD implementation for ongoing SNF activities, managing SNF data and records.

Initiating a consolidated QA activities report which provides status of QA programs at HQ and at applicable SNF Sites.

Establishing lines of communication and identifying SNF points-of-contact.

Providing systems engineering integration guidelines.

Conducting QA and data reviews at the sites. Providing guidance based on review results.

Establishing SNF data proposed path forward based on reviews.

Conducting qualification audit and activities of the Operations Offices and its M&O contractors to verify QA program implementation in accordance with the QARD.

Fig 3

Fig 4

DATA QUALIFICATION PROCESS

QA records are completed documents that furnish evidence of the quality of items and activities. SNF QA records are generated when SNF is handled, moved, characterized, or conditioned. QA records also are generated during the design, specification, and qualification of facilities or equipment involved with SNF disposal. SNF QA records must be controlled to ensure that information is accurate and available for use in support of the eventual disposition of SNF in a disposal facility. Accordingly, each SNF site will implement a records management system specifically for the DOE SNF Program.

Records generated prior to development of the DOE SNF Program also may be needed to support interim storage and ultimate disposition of SNF. Until RW identifies all SNF information needs, sites will ensure that previously generated records are protected from damage, loss, or destruction. When these records are used to support interim storage or ultimate disposition of SNF, they will be validated as QA records and managed under each site's QA records program.

The Integrated Spent Nuclear Fuel Database System (ISNFDS) was developed as a management tool specifically for EM-67 as the single source of data for management planning during disposition of DOE's SNF. The ISNFDS now contains information on most DOE-owned SNF. Data in the ISNFDS needed to support acceptance of SNF in a geologic repository will be qualified to requirements of the QARD by the SNF sites. The ISNFDS will be updated with qualified data which will then be made available to the Unified Database under development by RW.

VISION FORWARD: SNF QA INITIATIVES

The QMP will formulate national Program QA management and oversight strategies and define the site-specific QA implementation strategies necessary to accomplishing the SNF Program mission. All site-specific SNF activities will be categorized using the SNF systems engineering process to identify the applicable QA implementation standards. The SNF Program has selected the RW QARD for SNF activities affecting interim storage or final disposition of SNF, from assuring existing storage through achieving interim storage to preparing for final disposition. QA controls will be applied in a graded approach consistent with, and as defined by, the applicable implementation standards.

Implementation of the RW QARD must be performed at the Sites to cover ongoing quality activities, such as the TRIGA cask loading at DOE Richland, the lab studies at DOE Savannah River, and the canning and conditioning at INEL as fuels are moved from wet to dry storage.

The SNF QA Program has projected a number of activities and initiatives for Fiscal Years 1996 and 1997. However, these plans may require

significant modification and updating in light of the uncertainties associated with various reductions in both EM and RW budgets.

APPLICATION OF QUALITY ASSURANCE CONTROLS TO TBM TUNNELING ON THE YUCCA MOUNTAIN PROJECT

Jon D. Christensen
Parsons Brinckerhoff Energy Services, Inc.

ABSTRACT

As part of the Yucca Mountain Project (YMP), a 7.62-meter diameter tunnel is being constructed using a Tunnel Boring Machine (TBM). This tunnel, which may form a portion of a permanent high-level nuclear waste repository, is being constructed under the auspices of a nuclear quality assurance (QA) program. The YMP nuclear QA program applies to items and activities determined to be important to radiological safety, waste isolation, and potential interactions with the environment. The items and activities determined to be important have been assigned a quality assurance classification. This paper focuses on the items (rockbolts, steel sets, and shotcrete) and quality affecting activities involved in providing ground support and excavating the tunnel. Typical activities that have been assigned QA classifications include TBM maintenance, control of water used in the tunnel during construction, and control of diesel emissions in the tunnel. The paper concludes that the key to the successful implementation of nuclear QA requirements for tunneling at Yucca Mountain was the assignment of personnel with the appropriate mix of tunneling and nuclear experience.

OVERVIEW OF THE CONSTRUCTION PROJECT

The U. S. Department of Energy's Yucca Mountain Project (YMP) is being conducted to determine the suitability of Yucca Mountain, located northwest of Las Vegas, Nevada on the Nevada Test Site, as a high-level nuclear waste repository. As part of this project, an Exploratory Studies Facility (ESF) is being constructed to characterize the site and to form a portion of the permanent repository should the site be found acceptable. Construction of a 7.62-meter diameter tunnel and associated alcoves approximately 7.8 km in length is a major portion of the ESF. Kiewit/PB is responsible for the construction of the tunnel using a

design provided by the Management & Operating (M&O) Contractor for the Yucca Mountain Project, TRW Environmental Safety Systems Inc.

The tunnel is being excavated using a Tunnel Boring Machine (TBM). Ground support, in the form of rockbolts or steel sets (structural steel members), is installed as the TBM advances. Steel reinforced concrete invert segments and rail track are also placed as the TBM advances and provide the surface and track which support the TBM trailing gear. As can be seen from Fig. 1, the TBM trailing gear includes a mapping gantry used by scientists assigned to the project to conduct detailed geologic mapping of the ESF. Use of this mapping gantry allows the geological mapping to be conducted at essentially the same time as the tunnel is bored and prior to the installation of support utilities such as air and water lines, electrical cable, and the muck conveyor.

Fig. 1

As of December 1, 1995, close to 3.2 km of the approximately 7.8 km in the total tunnel loop had been constructed. It is planned that the tunnel be finished in calendar year 1996 or early 1997. The possibility exists that additional tunneling beyond that of the main loop may eventually be constructed.

QUALITY ASSURANCE REQUIREMENTS

ESF construction work is conducted by Kiewit/PB in accordance with specifications and drawings provided by the M&O Architect Engineer (A/E) organization. These specifications and drawings identify items and activities which have received a QA classification referred to as a 'Q' classification and fall under the auspices of a QA program required to be implemented by Kiewit/PB. 'Q' classifications include items and activities important to radiological safety, important to waste isolation, and important to potential interaction with the environment. Importance to radiological safety involves ensuring that spent nuclear fuel can be received, handled, packaged, stored, and retrieved without undue risk to the health and safety of the public. Because the ESF tunnel may become part of the permanent repository, this classification is applied to certain items providing ground support. Importance to waste isolation involves ensuring that barriers to prevent the migration of radionuclides remain intact during storage. Use of organic material which could degrade such barriers over time is limited and strictly controlled as a result of the application of this classification. Items whose failure could impair the ability of another item to perform its intended radiological safety or waste isolation function are classified important to potential interaction and also fall under the auspices of the QA program.

The overall QA program that is required to be applied to 'Q' classified items and activities for work at Yucca Mountain is defined in the U.S. Department of Energy Office of Civilian Radioactive Waste Management Quality Assurance Requirements and Description (QARD). This document is a compilation of the various regulatory and commitment documents regarding QA that are applicable to the YMP but is based primarily upon the following documents:

10CFR60, Disposal of High-Level Radioactive Wastes in Geologic Repositories, Subpart G - Quality Assurance

10CFR50, Appendix B, Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants

ANSI/ASME NQA-1(1989), Quality Assurance Program Requirements for Nuclear Facilities

NRC Review Plan (Rev. 2), U.S. Nuclear Regulatory Commission Review Plan for High-Level Waste Repository Quality Assurance Program Descriptions

Kiewit/PB has established Management Control Procedures which address and implement the QA requirements contained in the QARD. In addition, Technical Control Procedures have been written that define how quality-related work will be conducted by the construction forces and engineering support organizations. Quality Control Procedures have also been written that define how quality control inspections will be conducted and documented.

The overall Kiewit/PB organization includes a QA organization that reports on a day-to-day coordination basis to the Kiewit/PB Project Manager and to a corporate Quality Services Director on QA issues. The procedural and organizational structures of Kiewit/PB as they relate to QA requirements are similar as would be found for most organizations implementing nuclear QA requirements. Of greater interest as reported herein is how the nuclear QA requirements are applied to the construction of a tunnel and this is discussed in some detail in the following section.

APPLICATION OF QUALITY ASSURANCE REQUIREMENTS

The only hardware items that have received a 'Q' classification are those items providing ground support for the tunnel. These items are rockbolts, steel sets, and shotcrete. The use of shotcrete is minimized because of its impact on the geological mapping and evaluations being conducted by the scientific community. No quality-related shotcrete has yet been placed in the main portions of the tunnel and alcoves. A description of the application of quality assurance requirements to the procurement and installation of rockbolts and steel sets follows.

Rockbolts

Two types of permanent function rockbolts are currently being utilized for 'Q' applications. The first is Super Swellex which are manufactured by Atlas Copco and the second is a hollow core continuously threaded rockbolt provide by Williams Form Engineering Corporation. These two types of rockbolts are shown in Fig. 2 along with the required installation pattern for both.

Fig. 2

The Super Swellex bolts, three meters in length, are circular steel tubes, folded to reduce their diameter. They are placed in drilled holes and expanded using high-pressure water. The bolts expand and may compact weaker material surrounding the hole and adapt their shape to any irregularities in the hole. The resulting frictional and mechanical interlocking reinforce and increase the stability of the rock surrounding the drilled hole. It should be noted that rolled steel channels and wire mesh may be installed along with these rockbolts as necessary for personnel safety.Because the manufacturer of Super Swellex bolts does not have a nuclear QA program meeting QARD requirements, the rockbolts are purchased as 'commercial grade' off-the-shelf items. Upon receipt, the rockbolts are 'dedicated' for use in a QA-classified application by the conduct of special tests and inspections. These special tests and inspections are conducted by the Kiewit/PB Quality Control group upon receipt of the rockbolts at the site and must be successfully completed before the rockbolts are released by the Quality Control group for use. Specifically, Quality Control verifies that the rockbolts have not been damaged or contaminated and that the dimensions specified by the

manufacturer are correct. One bolt out of every 100 received is destructively pull tested to verify that it meets the manufacturer's published minimum breaking strength of 200 kN.

During installation, Quality Control Inspectors monitor that the holes drilled for the rockbolts are clean and free of loose debris and are located in accordance with design pattern requirements. In addition, Quality Control Inspectors monitor the installation of the rockbolts to ensure that they are being properly pressurized to a pressure between 290 and 310 bar using calibrated pressure gauges. This ensures that the rockbolts are being properly expanded during the installation process. After installation, five of every 100 rockbolts are nondestructively proof load-tested to verify that a specified load can be placed without exceeding a specified displacement of the rockbolt. Although the tests are performed by the construction force, the tests are witnessed and the results verified by Quality Control Inspectors.

The Williams hollow core continuously threaded rockbolts are initially anchored in place by the mechanical anchor head at the end of the bolt placed into the drilled hole. As a nut on the outside end of the bolt is tightened against a plate on the tunnel surface, the mechanical anchor expands against the sides of the hole and the bolt is set in place. The bolt is then grouted in place by pumping grout through the hole in the center of the bolt until the space in the hole surrounding the bolt is completely filled. As with the Super Swellex bolts, the supplier does not have a nuclear quality assurance program and they are purchased 'commercial grade' and dedicated by the Kiewit/PB Quality Control group by conducting special tests and inspections upon receipt at the site. The bolts are inspected and one rockbolt out of every 100 is destructively pull-tested in a manner similar to Super Swellex rockbolts.

During installation of the Williams rockbolts, Quality Control Inspectors monitor to ensure that the bolts are being installed in accordance with design pattern requirements, proper hole depths for the rockbolts are achieved, there is sufficient protrusion of the rockbolts from the holes to ensure proper nut engagement, and that the proper setting of the rockbolts is occurring by checking the setting torque using calibrated torque wrenches. Steel channels and wire mesh are installed along with these rockbolts as necessary for personnel safety. The Inspectors also verify that the grout is properly mixed, at the correct temperature, and pumped until there is a continuous grout return visible at the rockbolt bearing plate. In addition, Quality Control takes sample grout cubes during each shift of grouting operations, cures the sample cubes in accordance with specification requirements, and conducts break tests in a site laboratory operated by Kiewit/PB Quality Control to verify that the required compressive strength of 20.69 MPa is being achieved.After the grout has set for a minimum of 72 hours, nondestructive pull testing of five of every 100 rockbolts is conducted and the test results verified by Kiewit/PB Quality Control.

A recent specification change, currently under evaluation for impact, has reclassified steel channel, wire mesh, and short rockbolts, as 'Q.' These items, previously unclassified and only installed by Kiewit/PB as necessary for personnel safety, will now be required to be receipt inspected and dedicated, installed in accordance with work procedures, and have the installation monitored for adequacy by the Kiewit/PB Quality Control group.

Steel Sets

Steel sets are used as tunnel ground support in areas where the ground conditions are inadequate to allow the use of rockbolts. Steel sets are structural steel rings, made from W8 steel shapes bent or rolled to the proper diameter, set on the concrete invert segments, and expanded into place on the inside diameter of the tunnel surface as shown in Fig. 3.
Fig. 3
The rings are normally placed four feet apart (two-foot spacing is allowed) and lagging, in the form of steel channel or wire mesh, is placed between the rings as necessary to support the ground. As shown in Fig. 4, the rings consist of three main segments, bolted together, and four shorter segments used in conjunction with shims during the installation expansion process. Hydraulic jacks are used to expand the rings against the tunnel surface, shims added as necessary, and the expansion segments bolted together.
Fig. 4
Although the initial steel sets installed in the tunnel were manufactured by a supplier working under the Kiewit/PB QA program, most steel sets have been procured from fully qualified suppliers having QA programs meeting nuclear requirements. The Kiewit/PB QA organization conducts surveillance of these suppliers during the manufacturing process to ensure specification requirements are being met. Upon receipt of the steel sets at site, they are inspected by Kiewit/PB Quality Control for damage and spot-checked for correct dimensions, configuration, and adequate welding. Documentation supplied by the manufacturer, including material test reports, welder qualifications, nondestructive test results, inspection results, and nonconformances, is also reviewed by Kiewit/PB Quality Control when the steel sets are received.
During installation, Quality Control Inspectors ensure that steel set components are not damaged; correct components such as nuts, bolts, and washers are used; the jacking force used to expand the rings does not exceed the maximum specified value of 242 kN; the spacing between the steel set rings is correct and that the rings are not placed closer than four inches from the front or rear edges of the concrete invert segment; and verify that the bolts connecting the steel set segment pieces are properly tightened. The Inspectors also record the unique identification numbers stamped on each of the ring segment pieces. In addition, the installation of the lagging is monitored to ensure that it is properly installed and is not damaged.
Other construction activities, including shotcreting, drill and blast excavation of alcoves, and fabrication and installation of concrete invert segments, require Quality Control monitoring and inspection. Specifically, the Quality Control group performs civil testing related to these activities including aggregate gradation, moisture, slump, and concrete cylinder and shotcrete core strength tests as well as other specific installation inspections.
QUALITY ASSURANCE CONTROLS RELATED TO OTHER SITE ACTIVITIES
Numerous other QA Controls are detailed in the specifications that govern the overall construction activities being performed by Kiewit/PB. These activities do not require direct inspection or monitoring by the Quality Control group but must be performed by trained personnel working to approved procedures. In most cases, quality assurance records are generated as a result of these controls. The function of the Kiewit/PB QA organization, as it applies to these QA Controls, is to ensure that the required work procedures are developed, the procedures adequately address

the applicable specification requirements, and that the requirements of the procedures are being properly implemented by the applicable Kiewit/PB organization responsible for conducting the work. This is accomplished by conducting reviews of all procedures that address QA Controls and by conducting surveillance of the implementation of these procedures. In addition, the overall Kiewit/PB QA program is periodically audited by the Department of Energy to verify that this program is being effectively implemented. Examples of typical QA Controls follow.

The specifications contain a QA Control requiring that a procedure be developed to monitor tunnel alignment to ensure that the tolerances of the excavated opening are within one-half tunnel diameter (3.81 meters) of the line and grade shown on the A/E drawings. This procedure has been developed and implemented by the Kiewit/PB Construction Department Survey Group. The Kiewit/PB QA organization conducts periodic surveillances to ensure that the requirements of this procedure are being correctly implemented.

The TBM specifications state "Perform periodic maintenance based on manufacturer's recommended maintenance/surveillance frequencies, including, for example: cutter inspection, leak inspection, oil sampling, lubrication point inspection, belt tensioning, belt inspection, scrubber cleaning, parts replacement, belt placement, etc." The purpose of this QA Control is, by requiring periodic maintenance, to eliminate or mitigate leaks or other failures of the TBM that could occur as the result of equipment failures that would result in tunnel contamination by organic materials, i.e. hydraulic fluid. In response to this control, Kiewit/PB has developed a Technical Control Procedure titled "TBM Operating and Maintenance Procedure." The procedure requires daily, weekly, and 500-hour maintenance to be conducted using maintenance checklists. These completed checklists, along with other maintenance test documentation, become QA records. Maintenance is performed by the Maintenance group in the Construction Department. The Kiewit/PB QA organization conducts periodic surveillance to ensure the procedure is being followed and properly completed records are being accumulated.

Another example of QA Control is related to water usage in the tunnel. The specifications state in part "The amount of construction water lost in the 7.62-meter diameter Topopah Spring Loop excavation shall not exceed 7.4 m3 per linear meter of tunnel excavated. Verification that this limit has not been exceeded shall be performed for each working shift by dividing the total cubic meters of water lost during the shift (as calculated from the water balance) by the linear meters of tunnel advance for the shift and comparing this value to the above limit." This requirement is addressed in another Technical Control Procedure titled "Water Use and Control - Subsurface." The procedure is implemented by Construction personnel and Kiewit/PB conducts periodic surveillance to ensure that the required meter readings are being recorded, the calculations correctly performed, and the results properly documented as QA records.

A final example of a QA Control procedure involves control of diesel emissions in the tunnel. This control states:

"Engines for all diesel powered equipment used in the North Ramp and associated alcoves shall be maintained in accordance with the manufacturer's recommendations, including adjustment of the fuel system, proper maintenance of the engine air intake system and exhaust

conditioning system. Exhaust emissions shall be checked/ monitored prior to first use in the North Ramp and thereafter as follows:

a. When excessive emissions are visually observed (excluding warm-up periods or hard acceleration when smoking is normal)

b. Prior to taking the equipment underground following maintenance of any emission related engine system

c. At not more than 500-hour intervals (+ 5%) of engine operation."

The Control further states that exhaust emission constituents to be monitored include diesel particulate matter (DPM), oxides of nitrogen (NOx), sulphur dioxide (SO2), carbon monoxide (CO) and carbon dioxide (CO2). Again, these controls are addressed in a Technical Control Procedure titled "Diesel Exhaust Emission Testing, Monitoring, and Control Procedure." Results of emission tests are conducted and the results documented by Construction Maintenance personnel. Kiewit/PB QA conducts periodic surveillance of this testing to ensure that it is being properly conducted and documented.

In total, the specifications applicable to the Kiewit/PB scope of work contain over 600 QA Controls which must be addressed in QA, work, and inspection procedures.

CONCLUSIONS

TBM tunneling operations have now been underway for over a year at Yucca Mountain. During this time, a QA program based upon nuclear standards has been successfully applied to these construction activities. This program has been under constant scrutiny in the form of QA audits and surveillances by outside organizations. Few, if any, serious programmatic problems have been identified. Because personnel experienced with tunnel design and construction typically have little or no experience with nuclear quality assurance requirements and, because personnel experienced with nuclear QA requirements have little or no experience with tunnel design and construction, implementation of the QA program has not always been without pain. Overall, however, implementation has gone well by providing the proper mix of personnel with tunneling experience and personnel with nuclear experience. Providing the appropriate mix of experienced personnel at the earliest possible point in the design and construction process is the key to success on a project such as this. In addition, assigned personnel must be made aware of the necessity of relying on each others experience, whether nuclear or tunneling, to achieve project success.

London W1P 6BQ
England

ABSTRACT
UK Nirex Ltd (Nirex) is developing a deep repository for the disposal of intermediate level and some low level radioactive waste. Nirex is also responsible for producing standard designs of transport containers, including a range of reusable shielded transport containers (RSTC) which are being designed to meet IAEA Type B requirements. The contents of the RSTCs will normally be cemented ILW in either four 500 litre drums or a 3m3 box or 3m3 drum of similar outside dimensions to the four 500 litre drums in their transport frame.
This paper presents an analysis to demonstrate the performance of the RSTC and its contents during the fire test specified in the IAEA Transport Regulations. Temperatures, activity release and internal pressure have been calculated.
The thermal analysis was carried out using OASYS LS-DYNA3D, a finite element code for three-dimensional structural and thermal analysis. Since the IAEA Transport Regulations require an impact test to precede the fire test, the thermal models include the deformation resulting from a 9m drop on to a rigid target. Thermal insulation is provided on the surface of the container to limit temperature rises in a fire, particularly in the region of the elastomer seals. The effect of partial loss of this insulation in the impact has also been analyzed.
Temperature rises throughout the RSTC and four 500 litre drums of cemented sludge wasteform have been calculated. Activity release into the internal cavity of the RTC has been calculated from the waste temperatures and the results of small-scale tests on active waste samples, taking no account of the integrity of the welded stainless steel drums. Steam will be generated from the waste during the fire test, so the steam pressure has also been determined.
The analysis has demonstrated that temperature rises are acceptable, and that activity is only released from a small fraction of the waste volume that reaches elevated temperatures. The total release is well below the limit of 1A2 in one week. Steam pressure inside the RSTC is well within design limits and there is no significant increase in the leakage rate due to reduction in seal compression. These conclusions apply even with some loss of the thermal insulation.

INTRODUCTION

UK Nirex Ltd (Nirex) has been established by the UK nuclear industry, with the agreement of the UK Government, to develop and operate a deep repository in the UK for the disposal of solid intermediate and some low level radioactive wastes (ILW and LLW). Nirex is also responsible for developing an integrated transport system for the movement of waste from waste producing sites to the repository.
Reusable shielded transport containers (RSTC) will be required to transport some types of ILW and will comply with the requirements of the IAEA Transport Regulations (IAEA, 1990) for Type B packages. These include meeting containment and shielding requirements following an impact on to an unyielding surface from 9m and a subsequent 30 minutes, 8000C fully engulfing hydrocarbon fire.
The RSTC will transport ILW in either four 500 litre drums in a transport frame (stillage), or a 3m3 box or 3m3 drum. The RSTCs will be produced in a range of shielding thicknesses from 70mm to 285mm, to suit the requirements of the different waste streams. The RSTC development program has now reached a stage where a single preferred concept has been

adopted; Fig. 1 illustrates the 70mm and 285mm thick versions (RSTC-70 and RSTC-285).

Fig. 1

This concept has been designed so that the sealing function does not depend on the lid. Sealing is provided through the use of a stainless steel lid seal member (LSM) which is clamped to the body of the container and is independent of the lid. The lid is held in place by 24 radial chocks around the periphery. A shock absorber is attached to the underside of the LSM to protect it from damage by the RSTC contents in inverted impacts, and this also reduces the impact force transmitted by the contents to the lid.

A notable feature of the design is the solid metal flow shock absorbers on the four corners of the body. These limit the accelerations and impact experienced by the RSTC for any inverted orientation by deforming in plastic manner. A stainless-steel clad balsa shock absorber is attached to the top of the lid for lid-down impact attitudes.

To provide thermal insulation for the fire accident scenario the design considered in this paper includes an external intumescent coating, although alternative thermal protection methods are currently being considered. This coating does not significantly affect the thermal performance of the RSTC under normal conditions. However, under fire accident conditions, the thermal resistance of the intumescent coating increases as the material foams up. This limits the amount of heat absorbed by the RSTC and also the maximum internal temperatures.

Various aspects of the design have been described in detail elsewhere (Sievwright et at 1991; Smith et al 1992; McKirdy et al 1994). This paper presents the analysis carried out to demonstrate the performance of the RSTC during the 30 minute, 8000C fire test specified in the IAEA Transport Regulations (IAEA, 1990).

SCOPE OF THE ANALYSES

The RSTC thermal analysis carried out had the following objectives:

To determine the steady-state temperature conditions in the RSTC under IAEA specified ambient conditions for a Type B(U) package (+380C and specified solar radiation input).

To determine the transient temperatures in the package during and after the fire test, up to the point where steady-state conditions were reached once again. The steady-state conditions after the fire test were different from the steady-state conditions before the fire, because the intumescent coating layer has a higher thermal resistance after the fire.

To quantify the increase in temperature of the waste and the seal face due to loss of intumescent coating in an impact before the fire.

The calculated temperatures were used to determine the following information:

Quantity of steam released from the cement grout used to encapsulate the waste, and hence the pressure-time transient within the RSTC cavity.

Activity released from the waste packages into the cavity of the RSTC.

Thermal distortion of the RSTC.

Performance of LSM.

ANALYSIS METHODOLOGY

The IAEA Regulations specify that the thermal test must follow the impact tests; hence the thermal analysis must take account of impact deformation and possible loss of intumescent coating. An impact analysis was therefore carried out to obtain the deformed geometry of the RSTC prior to the start of the fire. One scenario examined involved an impact in a

lid corner attitude. This results in a large 'knock-back', and a loss of intumescent coating from the shock absorber close to the seal face, which would cause an increase in seal face temperatures. The amount of the intumescent coating lost was determined from separate tests. To quantify the effect of the loss of insulation, an impact damaged model with insulation intact was also analyzed.

The requirement that the thermal distortion of the RSTC and the performance of the LSM had to be evaluated implied that a thermo-mechanical finite element (FE) analysis of the RSTC was necessary. The finite element code chosen was OASYS LS-DYNA3D (Oasys Ltd, 1994). This code is renowned for its capabilities in analyzing non-linear dynamic problems. Recently its capabilities were extended to include thermal analysis by incorporating the heat transfer code TOPAZ3D (Shapiro, 1985). It is now possible to use LS-DYNA3D to perform fully-coupled thermo-mechanical analysis.

Prior to the commencement of the work it was decided that the most efficient way to carry out the analyses would be to use the same FE models for both the thermal and mechanical analyses. Figure 2 shows the finite element mesh for the RSTC-285 as an example. In general 8-noded solid elements were used. On some components where there was only a single layer of elements (eg the parts of LSM, and the stillage) a layer of shell elements was also used to ensure that the correct elastic stiffness was maintained. The bolts in the clamps holding the LSM to the body were modelled using spring elements. A plane of symmetry was taken through the damaged shock absorber, this reduced the size of the FE models by half. The total number of elements used in a half model was 57,044 for the RSTC-285 and 44,708 for the RSTC-70.

Fig. 2

All features of LS-DYNA3D that were used in the analyses were tested by running simple models and comparing the results with closed-form solutions. More complex models of actual physical tests were developed and results compared with those from tests, for example tests on 500 litre drums subjected to heating in a furnace. In this way it was possible to demonstrate with confidence that realistic results could be obtained from the full models.

Representative material properties were assumed, and other assumptions were based on the IAEA test requirements. The thermal properties of the wasteform were based upon those measured by Nirex for a cemented sludge wasteform (Bush et al 1990). The drums were assumed to generate a maximum of 50 watts each, which is the maximum permitted in the Nirex Waste Package Specification. The evaporation of steam from the wasteform was modelled by including a 'spike' in the specific heat of the wasteform at 1000C.

RESULTS

Normal Conditions of Transport

The steady-state analyses of an undamaged RSTC-285 and RSTC-70 for normal conditions of transport gave predicted maximum waste temperatures of 660C for the RSTC-285 and 650C for the RSTC-70. These maximum temperatures were located towards the top of the drums and are primarily related to the insolation, which is highest on the top surface of the RSTC (IAEA, 1990). It was predicted that steady-state conditions would be achieved after 35 days. Temperatures are highest near the center of the RSTC while the lowest temperatures are at the bottom corner of the drum. This indicates a temperature gradient which causes heat flow out of the drums

and towards the walls and base of the RSTC. The waste temperatures are acceptable because the maximum is well below 1000C, the temperature at which steam would begin to be driven of the cement matrix which immobilizes the waste.

Fire Test Conditions

The model used for the fire test analysis used as its initial conditions the calculated steady-state temperature distribution, together with the deformed geometry obtained from an analysis of a 9m lid corner drop onto an unyielding target. The effects of both undamaged and damaged intumescent coating were also taken into account. The stillage and drums were positioned as close as possible to the damaged corner so as to maximize the heat input to the waste.

Figures 3 and 4 show the predicted temperature distribution for the RSTC-285 and RSTC-70 with damaged intumescent coating at 5 hours after the commencement of the 30 minute fire. The corresponding temperatures for the undamaged intumescent coating are shown in Figs. 5 and 6. This was the time at which the temperature peaked. After the end of the fire, the heat absorbed by the RSTC flows into the waste as well as to the surrounding atmosphere, thus causing the peak waste temperatures to occur some time after the end of the fire. In these figures only the body of the container and the waste are shown for clarity.

Fig. 3

Fig. 4

Fig. 5

Tables I and II summarize the principal results. It can be concluded from these results that the only significant effect of the partial loss of intumescent coating on the shock absorber is to increase the peak temperature on the seal face of the RSTC-70 by 810C. The maximum temperatures of the waste for the RSTC-285 and RSTC-70 were 1200C and 1070C respectively and occurred after 5 hours. Table III summarizes the strains in the major RSTC components resulting from the thermal transient for the undamaged intumescent coating scenario.

Tables I and II show that the predicted activity releases into the RSTC cavity are three orders of magnitude below the limits for release from the package as a whole. Therefore the performance of the seals is not critical in this scenario.

Table I

Table II

The RSTC-70 with damaged intumescent coating had the highest seal face temperature of 1820C. This is due to having a smaller wall thickness and hence a shorter heat path to the seal face. The temperature-time history of the seal face is shown in Fig. 7. In tests (McKirdy et al 1994) the candidate seal was subjected to 5 hours at 2000C with satisfactory performance. Hence the seals will still be effective in providing containment to the RSTCs after the fire.

Fig. 6

Fig. 7

The analysis showed that the current designs of RSTC-285 and RSTC-70 with damaged intumescent coating are capable of satisfying the IAEA fire test requirements (IAEA 1990) following an impact from 9m on to an unyielding target.

A VALIDATED IMPACT ANALYSIS MODEL FOR ILW TRANSPORT CONTAINERS

I. L. S. Gray

England

ABSTRACT

UK Nirex Ltd (Nirex) is developing a deep repository for the disposal of intermediate level and some low level radioactive waste. Nirex is also responsible for producing standard designs of transport containers, including a range of reusable shielded transport containers (RSTCs), which are being designed to meet IAEA Type B requirements. The contents of the RSTC will normally be cemented ILW in either four 500 litre drums, or a 3m3 box or a 3m3 drum of similar outside dimensions to the four 500 litre drums in their transport frame.

This paper describes the development of a validated impact analysis model for the RSTCs, based on predicted and measured results for one-third-scale models with two different shielding thicknesses.

Decelerations, strains and local impact deformations have been both measured and predicted, for a series of drop tests from 9m which comply with the IAEA Transport Regulations. A finite element model has been developed using the DYNA3D code, which can model the large plastic strains and transient loading within acceptable computing times.

The model has been validated in the following respects. It can accurately predict the extent and shape of knock-back displacements in the impact zone. The model can predict deceleration transients reasonably well, with good agreement when both the measurements and the predictions have been processed by low-pass filtering. Strains are predicted with varying levels of agreement, partly because the predictions are for the centroids of elements, and not for the surfaces where the strains were measured.

INTRODUCTION

UK Nirex Ltd (Nirex) is responsible for developing and operating a deep repository in the UK for the disposal of intermediate and some low level radioactive wastes (ILW and LLW). Nirex is also responsible for producing standard designs of waste packages and transport containers, as well as the development of an integrated transport system for the movement of waste from waste producing sites to the repository.

For the transport of some types of ILW, reusable shielded transport containers (RSTCs) will be provided. The RSTCs are designed to comply with Type B requirements of the IAEA Transport Regulations (1). Nirex is currently developing RSTC designs in a range of shielding thicknesses, ranging from 70mm to 285mm for this purpose, depending on the waste stream. The possible contents for the RSTCs are four 500 litre drums in a transport frame (stillage), a 3m3 drum or a 3m3 box.

The RSTC development program has now reached a stage where a single preferred concept has been adopted. Figure 1 shows the 285mm and 70mm versions (RSTC-285 and RSTC-70). The key features of this design are:

The lid is retained by 24 cam-operated chock mechanisms arranged at 300 to the horizontal, and can be lifted and handled using the pintle. A stainless steel clad balsa wood shock absorber is located on the top side to limit impact forces.

The lid has no sealing function in this design. Sealing is provided by the lid seal member (LSM), which is a thin plate containing O-ring seals in a thicker outer rim, which is clamped to the body. An internal shock absorber is attached on the underside of the LSM to protect it from damage by the RSTC contents during impact.

Primary protection for lid-down impact orientations is provided by the solid metal shock absorbers which are located at the corners of the container. In impact these deform plastically and hence act to reduce the decelerations on the RSTC.

Fig. 1

Various aspects of the design have been described elsewhere (2,3,4). This paper describes the development of a validated impact analysis model for the RSTC, based on measured results from a series of IAEA regulatory drop tests on one-third-scale models of the RSTC-70 and RSTC-285. The purpose of this was to develop and validate finite element (FE) models that could be used for predicting the effects of any subsequent design changes.

DROP TESTING

The IAEA Transport Regulations (1) require a 9m drop test onto a flat, rigid target in the least favorable impact attitudes. Compliance may be demonstrated by a combination of analytical modelling and practical drop tests. A series of fully-instrumented drop tests were there fore carried out on one-third-scale models of the RSTC-70 and RSTC-285, each carrying four one-third scale 500 litre drums in their transport frame.

The impact attitudes used in the drop tests were selected from the results of earlier analytical modelling, which showed that the potentially most damaging attitudes would be with the center of gravity over a lid corner or over a lid edge, or a flat impact on one side.

The drop test tower incorporated vertical guide rails, and runners were attached to the RSTC scale models to ensure that it did not rotate out of the desired impact attitude while falling. The last two metres of the drop test were in free-fall, but high speed photography showed that the correct impact attitude was achieved within a fraction of a degree.

The instrumentation included accelerometers and strain gauges connected to high-speed data recorders by a free-falling umbilical cable; for example Fig. 3 shows the locations of some of the accelerometers and strain gauges for the lid corner drop of the RSTC-70 model. Two high-speed cameras filmed each drop from orthogonal viewpoints and all image frames were accurately timed. Each drop was also recorded using a video camera. Several reference points were scribed on the container body and lid to enable any distortions resulting from the drop to be established by physical metrology.

The instrumentation provided data that could be compared directly against the predictions of the finite element (FE) models described below. The results of the drop testing are presented as part of the comparisons with the model predictions.

DEVELOPMENT OF FINITE ELEMENT MODELS

FE models were generated for the two containers of different nominal wall thickness for each of the three impact attitudes. The models were analyzed using DYNA3D (5).

The FE analyses were based on the same basic model which is an eighth slice of the RSTC. This section was then rotated and reflected to generate the required model. It was assumed that all impact damage would be symmetric and hence it was only necessary to model one half of the RSTC. It was recognized that the RSTC could bounce and impact again in a non-symmetric manner but at this late stage (typically after 0.1 seconds) the majority of the available impact energy would have been absorbed.

To simply the analysis it was assumed that the drums and frame would act as a solid mass, and that the drums could not move relative to each other. For lid corner and lid edge impact, the mass of the frame and drums acted continuously on the internal shock absorber as a single mass. Therefore it was not possible to measure drum movements. However, visual examination after the tests showed that in most cases the drums remained tightly fixed in their frame.

The containment integrity was determined after each drop test by a gas leak test. To attempt to model the actual behavior of the LSM in the FE analysis would require a very detailed model and it was assumed that the LSM rim remains in position and does not move relative to the RSTC, and so the clamping mechanism was not explicitly modelled.

The wooden shock absorber on the lid was also omitted because it does not affect the structural response of the RSTCs in the impact attitudes modelled. The steel and concrete target used in the drop tests was modelled explicitly, since it cannot be assumed that any practical impact target is 'rigid'.

Appropriate material properties were used throughout the FE models. The upper parts of the external shock absorber 'ears' (Figs. 1 and 2) were modelled with strain-rate enhanced yield stresses, and the internal shock absorber was modelled with a constant crush stress.

Fig. 2

Fig. 3

Measured coefficients of friction between the RSTC and the target are not available. Analysis of the results of the first drop test indicated that a value of 0.15 gave good agreement, and the same value was used for all other tests. Elsewhere in the model, the same value was used for other coefficients of friction, with two exceptions. Instead of modelling the lid-retaining chock mechanisms, the coefficient of friction around the chock locations was increased to 0.75 to give an adequate representation

of the chock performance. Friction was excluded from the contacts between the transport frame and the RSTC cavity walls, ensuring that the full weight of the RSTC contents could act on the internal shock absorber. For both the RSTC-70 and RSTC-285, the following impact attitudes were considered, in each case for a 9m free drop producing an impact velocity of 13.3m s-1.

1. Lid corner - The plane of symmetry cuts diagonally through from the impact point to the uppermost base corner (Fig. 4). The contents have already slid down to rest against the interior shock absorber. The model consisted of 11297 elements.
2. Lid edge - The plane of symmetry cuts through the center of the RSTC from the impact edge to the uppermost base edge and both corner shock absorbers contact simultaneously. The contents have already slid down to rest against the interior shock absorber. The model consisted of 13340 elements.
3. Flat side - The contents are resting on the impact side. The model consisted of 16017 elements.

The accuracy of a finite-element model is dependent on the mesh size, mesh density, geometrical accuracy and assumptions regarding elastic and plastic material properties, friction, and strain rate dependency. Sources of experimental inaccuracy include; asymmetry of impact; the positions of strain gauges and accelerometers, and how rigidly they were attached; timing the moment of first contact; the settings and performances of trace filtering hardware; damage to the impact area during secondary impacts following the main rebound; and the cumulative deformation of scale models that had been dropped more than once. These were taken into account in developing the FE models, as far as possible.

Fig. 4

VALIDATION OF MODEL

The key parameters for validating the FE model are knockback (ie permanent deformation of the impact area), accelerations and strains. Owing to the volume of data generated for the two wall thicknesses, each dropped in three attitudes, only a summary is given here.

A major approximation in the validation was that although the same scale models were used for more than one drop test, the FE models were assumed to be undistorted. Post-test metrology supported this assumption because permanent distortions outside of the impact area were minimal, and the RSTCs were always dropped onto undamaged areas.

The duration of the primary impact for all three attitudes was in the region of 10msec. The measured deformations in general agreed very well with the predictions, both in shape and in the extent of knockback from the unperformed profile. For the 9m lid corner and lid edge attitudes a comparison of predicted and measured knockback of the metal shock absorber is provided in Table I. Agreement in the deformation results was within 5mm. Variations between the results are consistent with the RSTC-285 being heavier than the RSTC-70, and the fact that in the lid edge attitude two shock absorber are activated as opposed to one for the lid corner. In a flat side impact, energy is absorbed by the deformation of the ribs on the side of the RSTC; good agreement was again achieved.

Table I

All accelerometer traces were low-pass filtered with a cut-off frequency of 400Hz because filtered traces can be compared more readily with filtered acceleration data from the FE model. A representative selection of plots comparing predicted and measured accelerations are shown in

Figs. 5 and 6, for the two RSTCs and the three impact attitudes. In general good agreement was obtained both in the timing and magnitude of the peak accelerations.

Fig. 5

Fig. 6

The maximum accelerations for the RSTC-285 in the lid corner and lid edge attitudes were 300g and 400g respectively. The correlation for the RSTC-285 flat side impact does not show good agreement because the RSTC in the test did not land quite squarely on all the ribs together. This could not be represented in the FE analysis, as symmetry boundary conditions were applied. The maximum acceleration was 1400g.

The maximum accelerations for the RSTC-70 were 520g in lid corner attitude, 620g lid edge attitude and 1200g in the flat side attitude. Measured strains and deformation contours detected small asymmetries in the way the containers landed on most occasions. In the FE model the areas of the container that remain elastic are more subject to numerical 'noise' in the strain data than those in areas of higher deformation, but the measured traces for the gauges in the elastic regions generally changed from compressive totensile near the times predicted by the model. Measured strain rates up to 100 s-1 were recorded; no gauges could be mounted at the points of impact but predicted strain rates in these areas were of the order of 4000 s-1 for the 70mm container and 1600 s-1 for the RSTC-285.

There was reasonable agreement in strain gauge data. Known sources of inaccuracy from the model are the use of straight-sided elements to represent curved surfaces such as the corner shock absorbers, and the fact that the model calculates strains at the centroid of the 3-D 'brick' elements whereas all measurements were made at the surface. This could be overcome by coating the surface with thin 'shell' elements. Because of the large variations in strains encountered at a single point (eg -1000me for one gauge) and the high strain rates (up to 4000 s-1) the use of finite elements closer in size to the strain gauges themselves would give more accurate results.

CONCLUSIONS

Both FE models have been validated in the following respects:

1. The extent and shape of knockback displacements in the impact zone can be accurately predicted, generally to better than 5mm.
2. Deceleration transients in terms of duration and magnitude showed good agreement between measurements and predictions.
3. Strains are predicted with varying levels of agreement, partly because predictions are for centroid of elements and not for the surfaces where strains were measured.

This work has demonstrated that the FE method can be used successfully and with confidence to predict the acceleration, knockback and extent of local plasticity for an RSTC.

ABSTRACT

Previously, we have investigated the sensitivity of RADTRAN accident-risk results to the required input parameters and studied key variables using Latin Hypercube Sampling (LHS). A general conclusion of this work is that the total risk uncertainty does not become excessive when rather conservative distributions are used to describe input parameters such as atmospheric turbulence conditions, highway accident rates, population densities, and package release fractions. However, packaging release fractions, which correspond to the spectrum of accident severities, typically range over a few orders of magnitude, and modeling their values with the simplest distribution functions was unsatisfactory in some respects. Because efforts to calculate release fractions are greatly complicated by the large varieties of packaging characteristics and detailed accident conditions that may affect the outcome, explicit inclusion of uncertainty by use of LHS and modeling of physical conditions through improved choice of distribution shape appeared to be a productive course.

We describe tests of more complex distribution functions, such as Lognormal and Bounded Normal, in fitting the point estimates of release fraction values. These distributions and their descriptive parameters were used as input parameters to Sandia National Laboratories' Latin Hypercube Sampling code to generate 100 sets of RADTRAN 4 input parameters used together with point estimates of other necessary inputs to calculate 100 observations of estimated accident dose risk. This procedure was applied to several distinct transportation situations to reveal the statistical uncertainty of accident-risk estimates calculated by RADTRAN 4. These results are in turn compared to previous results, obtained with simpler Uniform and Loguniform distributions, to assess potential improvements in statistical behavior and absolute risk estimates.

Difficulties encountered and examples of cases that yielded improvements are presented for Type A and Type B packagings employed in representative truck transport situation.

INTRODUCTION

One of the choices that must be made in using Latin Hypercube Sampling (LHS) (1) with the RADTRAN Code for transportation risk assessment (2) is the type of distribution function to use in describing the uncertainty of a particular variable. Four options available with LHS are Uniform, Loguniform, Normal and Lognormal distributions; these adequately describe the uncertainty of most of the RADTRAN variable types selected for LHS analysis (3). These include the Pasquill probability fractions which have been described by Uniform distributions of values between 0 and 1. The uncertainty in two other variable types, link population densities (LPOPD) and link accident rates (LARAT), have been described by Normal distributions since, in general, they are averages with standard deviations obtained from the census and other surveys.

In previous work (3,4), release fraction (RFRAC) parameter values (the source terms for subsequent dispersion), were modeled by Uniform or Loguniform distributions spanning one or more orders of magnitude. Those studies demonstrated that Loguniform distributions yield smaller average risk estimates than Uniform distributions, in agreement with expectation, but the variances were large, especially if the loguniform distribution spanned more than one decade. The release fractions employed in a RADTRAN calculation are critical in determining the resultant risk but experimental measurement of releases from particular packagings under various accident conditions is very costly in time and money. Therefore, improved, conservative modeling of releases that will not generate inflated risk estimates or variances, and that can be derived by extrapolation of existing data is quite desirable.

The results of modeling release behavior of Type A and Type B packagings by use of available distribution shapes and widths are presented here. In addition, we discuss investigations of the effect of aggregating uncertainty by reducing the number of severity levels and modeling the change of release fraction versus severity level with a selected distribution shape. The goal in all cases was to maintain reasonable conservatism without introducing excessive uncertainty in the risk estimates.

SHIPMENTS OF TYPE A PACKAGES

The spectrum of severity levels and corresponding release fractions for this type of package may be divided into eight levels with the lowest level having no release (5). The increase in release fraction over the remaining seven levels is then defined according to the specific nature of the shipment being analyzed. For the examples presented here (multiple Type A packages), the highest five severity levels result in 100% release of the package contents; this suggested simplifying the analysis by reducing the spectrum of severities to three levels and modeling the corresponding release fractions by various distribution functions. The results of modeling the spectrum of release fractions with Uniform and Loguniform distributions over the indicated ranges are shown in Table I. The characteristic difference between these two types of distributions is evident in the shifted mean risk values and increased standard deviations for the Lognormal cases. Results obtained with Normal and Lognormal distributions in the three-level scheme are shown in Table II.

Table I

Table II

SHIPMENTS OF TYPE B PACKAGES

Calculations of risk estimates for a standard test case have been performed using various specifications of all four distribution functions

examined. This case is particularly instructive because it describes shipments of spent nuclear fuel (SNF) and CRUD (scale containing cobalt 60 which is deposited on the exterior of the fuel cladding during pool storage). The magnitudes of accident risk estimates calculated for such shipments are determined almost entirely by CRUD release. We again investigated potential simplification through aggregation of uncertainty in a reduction from six severity levels (6) to four. Tables IIIa and IIIb illustrate how the severity fractions of levels 4, 5 and 6 were summed to yield one level while levels 1, 2 and 3 include nearly 100% of accidents. In the case of CRUD, level 3 (in addition to 4, 5 & 6) results in release because it is external to the full cladding; past practice has been to assign these levels a release fraction (1.2E-2) that corresponds to total release of all suspended material inside the cask. This has been recognized as an extremely conservative model for the vast majority of accidents. For the current calculations, this value was taken as the maximum and the increase from 0 to 1.2E-2, over the range of severity levels, was modeled by a variety of distribution (and sampled by LHS). The results of calculations with the various distribution functions and defining parameters are given in Table IV.

Table IIIa

Table IIIb

Table IV

CONCLUSIONS

For Type A packagings, comparison of the results in Table I indicates that neither Uniform nor Loguniform distributions in a three-level scheme provide a fully satisfactory model in that average risk values tend to increase slightly and the standard deviations increase significantly, especially in the case of the Loguniform distribution. Use of Normal distributions yields results (Table II) which are similar to those for the Uniform and Loguniform distributions without the large standard deviation of the Loguniform case. Finally, use of a Lognormal distribution gives values which are very similar to the 8-level results with a modest increase in standard deviation.

For Type B packagings, the values shown in Table IV clearly show that use of the Loguniform distribution over a parameter range of many decades has two effects: it lowers the average significantly but the fractional standard deviation (%) is in turn increased significantly. The large standard deviation is exacerbated by the fact that the risk is dominated by one distribution: CRUD release. It seems that a more satisfactory means of reflecting the statistical prevalence of lower RFRAC values is to employ a Bounded Normal distribution with the mean at the lower end of the desired RFRAC range. Use of the Bounded Lognormal distribution provides even further improvement in that the averages are comparable to the 6-level values and the relative standard deviations are less than those for the other distributions.

In general, it is concluded that distribution functions available in the Latin Hypercube Sampling code can be used to model the increase of release fraction with increasing accident severity. Inexactness in knowledge of the scaling with discrete severity levels can be addressed by aggregating them into combined severity levels. Most importantly, in many cases the least specific distributions (Uniform and Loguniform) can be employed without altering average risk estimates significantly or producing such large relative standard deviations as to diminish the

value of the analysis, while at the same time permitting the analysis to be simplified.

INVESTIGATION OF RADTRAN STOP MODEL INPUT PARAMETERS FOR TRUCK STOPS*

N. R. Griego
J. D. Smith
K. S. Neuhauser
Sandia National Laboratories
Transportation Systems Analysis Department
Albuquerque, NM 87185-0718

ABSTRACT

RADTRAN is a computer code for estimating the risks and consequences associated with the transport of radioactive materials (RAM). RADTRAN was developed and is maintained by Sandia National Laboratories for the U.S. Department of Energy (DOE). For incident-free (i.e., no transportation accidents or off-normal occurrences) transportation, the dose to persons exposed while the shipment is stopped is frequently a major percentage of the overall dose. This dose is referred to as Stop Dose and is calculated by the Stop Model. Because stop dose is a significant portion of the overall dose associated with RAM transport, the values used as input for the Stop Model are important. Therefore, an investigation of typical values for RADTRAN Stop Parameters for truck stops was performed. The resulting data from these investigations were analyzed to provide mean values, standard deviations, and histograms. Hence, the mean values can be used when an analyst does not have a basis for selecting other input values for the Stop Model. In addition, the histograms and their characteristics can be used to guide statistical sampling techniques to measure sensitivity of the RADTRAN calculated Stop Dose to the uncertainties in the stop model input parameters. This paper discusses the details and presents the results of the investigation of stop model input parameters at truck stops. The current investigation was limited to

refueling stops, but the methodology developed can be applied to stops with other purposes.

INTRODUCTION

The objective of this investigation was to determine statistically meaningful estimates of the average values of the parameters which affect the calculation of stop dose at truck stops. Stop parameters observed for trucks in general are considered to be representative of RAM transportation trucks specifically because whether or not a truck actually carries RAM should not affect its time to refuel. This investigation has not attempted to characterize road-side stops or stops at any other location than truck stops.

To begin this investigation, it was necessary to identify which parameters affect the stop dose. This was accomplished by studying the documentation supporting the RADTRAN Stop Model (1) and an earlier investigation "Truck Transportation of Radioactive Materials" (2). The parameters identified as most directly affecting stop dose are: the duration of the stop, which is referred to as Stop Time; the number of persons exposed to the truck while it is stopped, which is referred to as Number of Persons Exposed (NPE); and the distance from the truck to the exposed persons, which is referred to as Exposure Distance. The NPE can be divided into people outside at the truck stop (i.e., without radiation shielding), and people inside buildings at the truck stop (i.e., with radiation shielding). Thus, the NPE should be observed as two parameters: NPE-outside, and NPE-inside buildings. In addition, the building materials should be noted as they could affect shielding values.

The prototype RADTRAN 5.0 Stop Model allows two options for specifying the NPE at a stop: 1) User specified number of people at a fixed exposure distance from the RAM shipment; and 2) a user specified number of people within an annular region with user specified minimum and maximum exposure distances (3). In addition, RADTRAN 5.0 allows for up to 20 distinct stops to be modeled in a single RADTRAN run. Hence, a refueling stop can be modeled with separate input values than a weigh station stop or a repair stop. A stop during peak time (with respect to congestion at the truck stop) can be modeled separately from a stop during off-hours.

To determine the range of values possible for the Stop Model input parameters, factors expected to affect these input values were identified. Factors possibly affecting Stop Time, NPE, and Exposure Distance include: truck stop location (i.e., rural, urban, or suburban, proximity to other commercial establishments, etc.); time of day; and purpose of the stop (i.e., refueling, service, etc.). Truck stop location is likely to affect the amount of business at that stop and, hence, the number of persons potentially exposed as well as the amount of time needed for service and potential for delays. Time of day was expected to have a similar effect. Truck stop location could also affect the configuration of the truck stop and, hence, the exposure distances. For example, land availability may affect the square footage occupied by metropolitan and rural truck stops, which could in turn, alter the distances between refueling bays, service bays, and restaurants, etc. The purpose of the stop is expected to affect the stop time. For example, a simple refueling stop is likely to be of shorter duration than a stop requiring repair service.

The stop times measured in this investigation were limited to refueling stops because all transports of sufficient distance must refuel, whereas a service stop may be unnecessary. Also, a refueling stop is most likely

of shorter duration than a service stop. Therefore, a refueling stop is a reasonable representation of a routine minimum stop time. Because the RADTRAN 5.0 Stop Model allows for up to 20 distinct stops to be modeled in a single RADTRAN run, the RADTRAN analyst can select a larger stop time when modeling a service stop. The observations of exposure distance and NPE should be applicable to all stops that occur at truck stops.

The actual investigation included traveling to truck stops and measuring stop time, number of persons exposed, and exposure distance. Truck stops were selected in several locations and observations were made at various times of the day and on various days of the week to yield a representative sample of truck stop parameters.

TRUCK STOP OBSERVATION PROTOCOL

A truck stop observation protocol was necessary to help ensure consistency in observation techniques between different truck stops, and to help ensure statistical soundness of the resulting data. We observed each truck stop anonymously so that our presence would not alter the data (i.e., the fuel pump attendant doesn't alter his or her pace, etc.). To avoid any unintentional preferential treatment in selecting which trucks to observe, we decided to measure stop time for every truck that refueled during each observation period. Two persons were involved in performing these observations and were present at each observation. To help ensure uniformity, each person performed the same duties at each observation.

Preliminary truck-stop observations were performed at two truck stops in Albuquerque, New Mexico, and at one truck stop in rural Arizona (Holbrook). The purpose of these preliminary observations was to familiarize ourselves with the conditions at truck stops so that we could develop an efficient and uniform plan for observing data at various truck stops. Based on these preliminary observations, an observation ledger form was developed to help ensure consistency between observations at each stop. The observation form included columns for observing the following variables: truck stop location; observation date; day of week; time of day; stop time; NPE-outside; outside exposure distance; NPE-inside buildings at the truck stop; building material(s); number of trucks parked in the first row (with respect to the refueling bays); distance from the refueling bays to the first row of parked trucks; paving material; and a section for comments. A free-hand sketch of the configuration of each truck stop was also prepared for each truck stop. A video camera was used to record the truck stop observations and a stop watch was used to measure stop time. The video tapes and ledgers are part of the quality assurance file for this project. The observation data are stored in a spread-sheet file (Microsoft Excel) so that data can be added as additional observations are performed.

The number of parked trucks was noted because parked trucks may have one or more persons sleeping inside. These persons could be considered as a distinct subset of NPE-inside. All parked trucks were not counted because persons sleeping in the 2nd or further row of parked trucks would be shielded by the first row of parked trucks.

The exposure zone was defined as the area enclosed by major shielding objects such as building walls and the first row of parked trucks. Since most of the persons travelled from the parking areas to the buildings, the exposure zone was modelled as a circular region with the diameter being the distance between the buildings and the first row of parked trucks.

Preliminary observations indicated that tracking the exposure distance for each individual entering the exposure zone would be nearly impossible because most persons walked through the zone rather than occupying it in a stationary manner. The preliminary observations also indicated that the same individuals did not occupy the exposure zone during the entire stop time for any given truck: people entered and exited the exposure zone at various times during any given truck's refueling period. Therefore, the protocol for observing NPE was defined as follows: the number of persons in any portion of the exposure zone was observed, along with the approximate time that each person occupied the zone (which is referred to as residence time). Summing the residence time for each person observed in the exposure zone yields a time-integrated NPE, with units of NPE-time. Dividing the time-integrated NPE by the total observation time yields an equivalent number of persons occupying the exposure zone for the entire observation period, as if they were not travelling into and out of the exposure zone. With this method of calculating NPE, one person occupying the exposure zone for two minutes is counted the same as two persons occupying the exposure zone for only one minute. This is consistent with RADTRAN methodology because RADTRAN calculates population dose rather than individual dose. Also, this definition of NPE is compatible with the NPE Input Option 2 in the RADTRAN 5.0 Stop Model, in which the NPE is expressed as the number of persons in an annular exposure zone with a user specified minimum and maximum radius. The two NPE Input Options available in RADTRAN 5.0 are discussed in the Introduction section of this report.

In practice, it proved impossible to observe NPE separately for every truck in the refueling area, because there were frequently numerous trucks refueling at the same time or in over-lapping time periods. Therefore, the protocol was adjusted to track the NPE for an observation time period during which many trucks were observed individually for stop time. Each observation period was approximately 60 minutes in duration. Therefore, the data presented in the Results section will show more observations of Stop Time than NPE.

RESULTS

Upon completion of the Truck Stop Observation Protocol, the actual investigation was performed. The actual investigation included traveling to truck stops and measuring stop time, number of persons exposed, and exposure distance. Two metropolitan truck stops in Albuquerque, New Mexico (Fina and Union 76) and one rural truck stop in Tucumcari, New Mexico (Shell) were observed.

The Fina observations were performed on July 24 (Monday), July 27 (Thursday), July 28 (Friday), August 1 (Tuesday), and August 2 (Wednesday) 1995. To provide a sampling of times-of-day, these observations were performed in the mornings and afternoons. The Union 76 observations were performed in the mornings of August 29 (Tuesday), September 6 (Wednesday), and September 7 (Thursday) 1995. The Shell observations were performed in the afternoon of October 23 (Monday) 1995. The average values, standard deviations, and number of observations for stop time, NPE-inside, and NPE-outside for each truck stop individually and for all three trucks stops as a composite, are listed in Table I. The number of trucks parked in the first row (with respect to the refueling bays) and the exposure distance for each truck stop individually and for the composite are also listed in Table I. The number of trucks parked in the first row is not presented as a statistical observation with numerous

observations because the value appeared to be constant for each truck stop; the first row was always observed to be full and, therefore, limited by the number of parking spaces in that row. The exposure distance for each truck stop is also not presented as a statistical observation because that value is constant for each truck stop, but depends on site-specific factors.

Histograms of the stop times for each individual truck stop and for the composite are shown in Figs. 1-4. The histograms and their characteristics can be used to guide statistical sampling techniques to measure sensitivity of the RADTRAN calculated Stop Dose to the uncertainties in the stop model input parameters.

Table I

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Discussion

The results listed in Table I indicate that the two metropolitan truck stops (Fina and Union 76) have nearly identical average stop times, average NPE-outside, and exposure distances, whereas the rural truck stop (Shell) has a lower average stop time, a lower average NPE-outside, and a larger exposure distance.

The exposure distances at both Albuquerque truck stops seem to be practical minimums because they represent the minimum distance needed to accommodate the number of refueling bays and a minimum lane width. The exposure distance at the Tucumcari truck stop is, indeed, larger than that at the Albuquerque truck stops.

Qualitative observations are useful for helping the analyst to design and perform analyses of truck stops. The first qualitative observations concern the refueling process. A general observation is that the truck stop employees work efficiently to refuel all of the trucks quickly. Dual fuel tanks were usually filled simultaneously; a separate fuel pump was used to fill each tank. Also, most of the truck drivers removed their trucks from the refueling bays promptly after the refueling was completed. All of these factors combine to minimize waiting time at the refueling bays. This is consistent with industry practice, as most truck drivers are concerned with travel time and strive to minimize their own delays and those of other truck drivers.

A second qualitative observation is that truck stops, in general, are quite busy. People concentrate around the restaurant, fueling area, mechanical shops, pay stations, and gift/supply stores. Numerous automobiles were observed parked at the restaurants at both Albuquerque truck stops, the Tucumcari truck stop, and the Holbrook truck stop. This indicates that people not associated with truck transport (i.e., local residents, automobile travellers, etc.) patronize the restaurants and other truck stop amenities. In addition, at the Albuquerque truck stops, people were observed walking through the exposure zone in route from one neighboring business to another; these people were not using truck stop services.

A third qualitative observation concerns trucks parked at the truck stop. The majority, approximately 90%, were equipped with "sleeper" cabins located aft of the crew cabin. This supports the concern that each parked truck could potentially contain at least one sleeping person who could be

exposed to a RAM transport. However, these persons would be significantly shielded by the tractor cab and engine compartment.

A last qualitative observation concerns building materials because they may affect shielding. Most of the buildings were of concrete cinder-block construction. However, some associated out-buildings such as the weigh-station booth, fuel payment-booths, etc., might be constructed of different materials providing less shielding.

SUMMARY

This paper discusses an investigation of stop model input parameters at truck stops. The parameters of stop time, number of persons exposed (inside building), and the number of persons exposed outside are presented as average values with standard deviations. Histograms of the stop data are presented as an aid for the analyst who may want to use statistical sampling techniques. The results presented in this report indicate that a metropolitan truck stop has a longer average stop time, larger average NPE, and closer exposure distances than the rural truck stop. However, fewer observations of the rural truck stop were performed than for the metropolitan truck stops. This data is stored in a spread-sheet file (Microsoft Excel). This format will allow new data to be added to the database as additional observations are performed.

DEVELOPMENT OF VITRIFIED WASTE STORAGE SYSTEM

Seiji Ohshima
Shigekazu Namiki
Yutaro Tani
Ishikawajima-Harima Heavy Industries Co., Ltd.

ABSTRACT

Ishikawajima-Harima Heavy Industries (IHI) has developed its own radioactive waste vitrification and storage technology. Concerning the vitrified waste storage system, IHI has developed and designed two type of storage systems. One is a forced convection air cooling system, and the other is a natural convection air cooling system. IHI has experimented and analyzed heat transfer, earthquake proofing, vitrified waste drop and radiation shielding, etc. In consideration of these understandings, IHI designed and constructed the first natural air cooling vitrified waste storage facility in Japan.

INTRODUCTION

The method of treating the high-level radioactive waste is that, to vitrified glass solidum to safe forms, and store the vitrified waste for 30 to 50 years for intermediate storage. Japan has two option program for vitrification, one is the domestic reprocessing plant, the other is the overseas reprocessing contract with COGEMA in France, and BNFL in England.

Ishikawajima-Harima Heavy Industries (IHI) has developed intermediate storage system, two of which are currently available. One is a forced convection air cooling system for domestic vitrification, and the other is a natural convection air cooling system.

CONCEPT OF STORAGE SYSTEMS

Regarding the design of the vitrified waste systems, some type of management systems can be provided. Table I shows the design concept of Vitrified Waste Storage systems (1). This classification takes notice of decay heat cooling function. To think about another functions following, enclose, shield, long time adaptation, economical adaptation, and so on. In these cases, vault air cooling systems have been validated by the following:

water cooling system is needed for the water circulation and the filter system.

the silo and the cask cooling system needs the large site area, and thus is not good for space efficiency. And the air flow is more complex than the inner flow in the annular tube.

Regarding the vitrified waste storage system is development, we have completed the design of two types of storage systems: one is a forced convection air cooling system (Fig. 1.), and the other is a natural air convection system (Fig. 2.) (1).

Table I

Fig. 1

Fig. 2

The forced air convection system is as follows: The vitrified waste is positioned in the tube directly the cooling air. The cooling air is induced by the ventilation system, which has blowers, filters, etc. and needs the electric power supply units. This system can perform without electric power, but needs emergency electric power. Because this system must be able to operate with the loss of the electric power supply. Therefore, the forced air convection air cooling system, adapts a small scale storage facility, because the ventilation system can be used in common with the storage area and other utilities, for example the vitrification cell. The natural air convection system is as follows: The vitrified waste is positioned in the thimble tube and the cooling air only contacts the outer surface of the thimble tube and not to contact the vitrified waste, so that the cooling air does not become contaminated. The decay heat is removed with the air flow induced by the draft force, which depends on the heat generation rate. The natural air cooling maintains a wide margin on acceptable vitrified waste for all site specific environmental conditions. And IHI has developed cooling properties, shielding, potential dropping and others for the natural air convection system.

The world experience of the interim storage facilities are: the forced air cooling system adopted by the A.V.M. (Atelier de Vitrification Marcoule) and the T.V.F.(Tokai Vitrification Facility), and the natural air cooling system adopted by the W.V.P.(Windscale Vitrification Plant) (1). And peculiarity IHI natural air cooling system is as follows: Each thimble tube is connected to the inner gas pumped down system, and the cavity at thimble tube is kept to negative pressure. The system can be designed to protect leakage from the vitrified waste containment boundary.

THE NATURAL AIR COOLING SYSTEM

The storage vault is shown in section in Fig. 3. The cooling air enters though a hood, protecting the wind and snow, and flows though a labyrinth and a louver which prevents radiation streaming and enters the storage area. The air flow of the storage area is as follows: The air in the annular gap between the thimble tubes and the ventilation pipes is heated

by the decay heat of the vitrified waste. Because of the density difference between the heated air and the open air, the draft force, due to the buoyancy, is generated in the annular gaps. And the cooling air takes decay heat from the vitrified waste, though the exit louver and labyrinth, up the concrete shaft and out to the atmosphere via a wind and snow hood. The flow rate of the cooling air increases as the heat generation rate of the vitrified waste becomes higher, and as the height of the annular gap and the air cooling outlet shaft increases.

Fig. 3

Estimating of the performance of natural convection air cooling system may be achieved by:

- thermo-hydraulic experimental testing about 1/3 scale models (2,3).
- development of thermo-hydraulic numerical analysis method (2).
- wind tunnel test to confirm the positive cooling effect of all directional wind conditions (3).

The thermo-hydraulic experimental apparatus is shown in Fig. 4. This basic model simulates three thimble tubes, and its scale is about 1/3. The heat generation rate of each thimble tube is controlled. The inlet flow velocity and the outlet air temperature of each annular tube is measured. And the experimental and the numerical results are shown in Fig. 5. Figure 5 shows the accuracy of the numerical method. This numerical method will applied to the facility design.

Fig. 4

Fig. 5

A low speed wind tunnel of 1/150 scale model simulates the storage facility and other buildings. The experimental parameter is in the shapes of the outlet shaft. The experimental result shows that the pressure difference of all the types is positive. These outlet shaft shapes increases the air flow rate.

Flow modeling of the vault module calculates both the general cooling air flow rate and particularly its distribution within the thimble tube. And the increase of the temperature inside the thimble tube has been carried out using the TAC-2D (4) code to calculate. The increase model of temperature inside the thimble tubes is shown in section is Fig. 6. And the calculation result shows that the decreasement of vitrified waste temperature by the storage years is Fig. 7 (5).

Fig. 6

Fig. 7

THE RADIATION SHIELDING

Most of the storage area are enclosed with concrete walls and floor, thus the radiation from vitrified waste is shielded in concrete. The natural air convection system have an inlet shaft and an outlet shaft for the cooling air. These shafts must be opened to the atmosphere, therefore, the both direct radiation and skyshine radiation, must be shielded to protect the environment. As the result of the shielding design, each shafts have louver and labyrinth. (See Fig. 3.) In the development of the vitrified waste storage technology, IHI compared the experimental data and calculation data (6). Figure 8 shows the experimental set up. An experiment was carried out to study the radiation distribution in a single bent duct and shielding effect of the louver. The single bent duct applied to the concrete duct for the ventilation system, and the louver applied to the inlet and outlet shaft for natural air convection system.

Fig. 8

THE POTENTIAL DROPPED ACCIDENT

The safety submission claimed that the single failure proof grab and hoist mechanism. The vitrified waste handling system is of sufficient integrity to render the probability of dropping the vitrified waste into the vault during loading operations, at nearly nil. To evaluate the potential consequences of dropping and possibly rupturing the vitrified waste; tests were run to an examination these consequences. It is assumed that the vitrified waste drops on the floor from the height of 9 meters, and drop on the previously stored vitrified waste in the thimble tube (3). The dropping velocity is an important parameter, and the calculated free dropping velocity from the height of 9 meters is about 13 m/sec, but the dropping velocity in the thimble tube is lower than that of a free drop because the narrow space between the dropping vitrified waste and thimble tube cause an air cushion effect.

The finite element grid is shown Fig. 9 and the numerical results are shown in Fig. 10 and 11.

Fig. 9

Fig. 10

Fig. 11

Figure 10 shows that the shoulder of the vitrified waste is deformed and Fig. 11 shows that the equivalent - plastic strain dose not exceed 20%. The numerical analysis result shows that the strain of canister does not exceed the tensile strain.

OTHERS

For design of the vitrified waste storage facility, following items are required.

The integrity during earthquake

Design criteria of the vitrified waste storage facility was established considering the special circumstances of Japan, such as limited site and strong earthquakes.

The concepts of operation

The vitrified waste is handled by remote control from a central control room. The central control room is equipped with three operational console and a watch foreman's console. Each operators console have a CRT units which is operated by a touch panel operation, and a ITV monitor.

DESIGN AND CONSTRUCTION

IHI designed and constructed the vitrified waste storage facility that is the first application of the natural air cooling system technology in Japan. The major specification of the JNFL's Facility are shown in Table II (5,7).

These appreciation for the Vitrified waste storage system will be applied to the design of the spent fuel storage facility. Development of the vitrified waste storage systems has been carried out IHI in order to obtain the design data and method of the spent fuel storage facility (8).

Table II

CONCLUSIONS

1) IHI has been designed and constructed two type of vault air cooling system for the vitrified waste storage facility. One is forced air cooling system, and the other is natural air cooling system.

2) Technology that carried out from the vitrified waste storage system development will be applied to the spent fuel storage system. And the concept design of vault air cooling system have been researched and developed.

ABSTRACT

Japan Atomic Energy Research Institute (JAERI) and Unitika Ltd. have jointly developed an inorganic adsorbent, which can remove plutonium (Pu) in reprocessing liquid waste and reduce a volume of the waste containing TRU by the incineration.

Previously We reported that this inorganic adsorbent had an excellent characteristics to adsorb Pu in the presence of 1 M nitric acid(1). We had done the flow-through column tests to determine practical conditions of the treatment process. From these results, this inorganic adsorbent was found to have good adsorption properties under the following conditions.

- adsorbent length / adsorbent diameter 3
- space velocity 1.6 h-1

The cold and hot incineration tests showed that the optimum conditions for the incineration of this fibrous adsorbent were that the temperature was 550C and the air flow rate was 30ml/min. We also found that the volume reduction factor was approximately 20 and no flying of adsorbed Pu was observed during the incineration process of the adsorbent.
This inorganic adsorbent has good characteristics to remove Pu directly without a pre-treatment of the liquid waste containing Pu, and reduce the volume of used adsorbent by the incineration. Therefore this process is very effective for the treatment of liquid waste.

INTRODUCTION

The radioactive liquid waste from reprocessing plants contains the fission products such as Cs, Sr and the TRU such as Pu and U. It is necessary to separate these products from the waste and to reduce the volume of the waste. The Coagulation-Sedimentation or the Ion-Exchange method had been conventionally used to treat the waste. However, these methods encountered the treatment of the secondary waste such as a sludge and the used resin itself, which shows only a small reduction of the volume by the incineration because of the flame retardant. The development of more effective adsorbent and treatment processes have been studied in order to overcome this shortcoming.
JAERI and Unitika had jointly developed an inorganic adsorbent, which is molded in the cartridge forms to be easily applied in the industrial fields. We made inorganic adsorbent by 80 wt% of fibrous adsorbent, that is, fibrous activated carbon which has the specific surface area of approximately 2,000 m2/g and 20 wt% of inorganic binder. The fibrous adsorbent was improved so as to be more hydrophilic by the oxidation without decrease of the specific surface area. As the fibrous adsorbent is consisted of more than 90% of carbon, it is physically and chemically stable, and easily converted to CO2 and H2O by the incineration. It is possible to expect useful applications form at the standpoint of the volume reduction of the waste.
In this paper, we report the Pu adsorption properties of the inorganic adsorbent and the incineration properties of this adsorbent.

EXPERIMENT

Adsorption Test

In the flow-through column test and equilibrium adsorption test, we used radioactive liquid waste as the test solution. The waste was spent-fuel generated from reprocessing at JRR-3 which is the first reactor in Japan. The properties of the liquid waste and test adsorbent are shown in Table I and II.
Table I
Table II

Equilibrium Adsorption Test

The immersion method was applied to the equilibrium adsorption test. The adsorbent was immersed in the test solution for 24 hours, and then the test solution was filtrated. Pu adsorption capacity of the adsorbent is obtained from the Pu concentration in the filtrate measured by a spectrometry.
The quantity of Pu adsorption is calculated as follows.
Eq. 1
Where :
QPu : Quantity of Pu adsorption (mg/g)
V : Quantity of solution (ml)
M : Quantity of adsorbent used (g)

C0 : Pu concentration of the test solution before adsorption (mg/ml)
C : Pu concentration of the test solution after adsorption (mg/ml)
The conditions of equilibrium adsorption test are the following:
Solution volume : 50 ml
Adsorbent weight : 0.1, 0.2, 0.5 g
Preservation time : 24 h
Flow-through Column Test
Figure 1 shows a diagram of the flow-through column test. We measured Pu concentration before and after the flow through of the adsorbent by a spectrometry.
Pu concentration ratio is calculated as follows:
Eq. 2
Where:
CPu :Pu concentration ratio
C0 :Pu concentration of the test solution before flow-through the adsorbent (mg/ml)
C :Pu concentration of the test solution after flow-through the adsorbent (mg/ml)
The conditions of flow-through column test are the following :
Adsorbent length / Adsorbent diameter : 6
Space velocity : 1.6 h-1
Adsorbent weight : 2.5 g
Fig.1
Fig. 2
Cold incineration Test of Inorganic Adsorption
Figure 2 shows a diagram of the incinerator used in this test. We used an inorganic adsorbent immersed in 1 M nitric acid in the cold incineration test.
The conditions of cold incineration test are the following:
Adsorbent weight : 1, 2, 3 g
Incineration temperature : 550, 600, 700C
Air flow rate : 5, 15, 30, 45 ml/min
Hot incineration Test of Inorganic Adsorption
We used an inorganic adsorbent immersed in test solution shown in Table I. We used an experimental apparatus similar to one shown in Fig. 2 in the hot incineration test of the inorganic adsorbent. We measured the radioactivity of the inlet, and the outlet glass-filter, at each point as numbered in Fig. 2 and the condensed water for the evaluation of the radioactive distribution.
The conditions of the hot incineration test are the following:
Adsorbent weight : 1.8 g
Incineration temperature : 550C
Air flow rate : 5, 15, 30 ml/min
RESULT
Equilibrium Adsorption Test
Figure 3 shows the adsorption isotherms of Pu at 20C. Table III shows the adsorption characteristics of b and g nuclide. The inorganic adsorbent molded in the cartridge forms was slightly less than the fibrous adsorbent in the quantity of Pu adsorption. The adsorption of b and g nuclide were not observed and it means that Pu was adsorbed selectively.
Table III
Fig. 3
Flow-through Column Test

Figure 4 shows a breakthrough curve obtained by the flow-through column test. The result shows that, the both adsorbents maintained a removing efficiency of approximately 97 % even when the volume of the flow-through liquid waste was 40 times that of the column.
Fig. 4
Cold incineration Test of Inorganic Adsorption
Figure 5 shows the effect of temperature on the incineration at the adsorbent weight of 2 g and the air flow rate of 30 ml/min. From this result, it was found that the incineration temperature did not affect on the rate of weight reduction of the inorganic adsorbent at the air flow rate of 30 ml/min, and also found that incineration was quite possible even at 550C (The ignition point of fibrous adsorbent is 480C).
Figure 6 shows the effect of the air flow rate at 550C. As the air flow rate increased, the rate of weight reduction became faster; however, over 30 ml/min, the rate of weight reduction became constant.
Figure 7 shows the effect of the adsorbent weight at the air flow of 30 ml/min and the temperature of 550C. The result shows that, when the adsorbent weight of 2 g and 3 g were used, the rate of weight reduction during the time elapsed of 1-5 hours coincided each other.
It was observed that the volume reduction factor was approximately 20 and no flying of particles and soot was observed with the incineration of this inorganic adsorbent.
Fig. 5
Fig. 6
Fig. 7
Hot incineration Test of Inorganic Adsorption
We evaluated the radioactivity distribution inside of a combustion pipe after the hot incineration test.
Table IV shows the radioactivity of glass-filters, Table V shows the radioactivity at each point as numbered in Fig. 2, and Table VI shows radioactivity of the condensed water which was generated at the incineration. From these results, we detected the radioactivity of Pu only in the residual ash but not inside of the pipe. This fact means that no flying of the nuclides was generated at the incineration.
Therefore, it is possible to incinerate the inorganic adsorbent at the air flow rate of 30 ml/min and temperature of 550C.
Table IV
Table V
Table VI
CONCLUSION
From the equilibrium adsorption test and the flow-through column test, we found that the inorganic adsorbent had an efficient adsorption properties on Pu. The incineration test of the inorganic adsorbent showed that volume reduction factor reaches approximately 20 and no flying of adsorbed Pu was observed.
These results suggest that the process using the inorganic adsorbent for the treatment of the radioactive waste is very effective from the standpoint of the volume reduction of the waste.
In the near future, this process will be applied for the treatment of stored liquid waste in JAERI.

EVOLUTION OF THE LR56 TYPE B(U) CASK SYSTEM FOR THE TRANSPORTATION OF RADIOACTIVE LIQUID WASTE

Gilles Clement
SGN
St. Quentin en Yvelines, France

Vijay Sazawal
Numatec, Inc.
Bethesda, MD, USA

ABSTRACT

The French Atomic Energy Commission (CEA) initially developed the LR56 cask system for off-site radioactive liquid transportation. Two models of this IAEA, type B(U) certified cask have been in day-to-day use in France and other European countries since 1988. Recently, the U.S. DOE decided to purchase two LR56 systems, one each for use at the Hanford and Oak Ridge sites. Modifications have been made to the original design (such as the addition of an integrated spray rinsing system for removal of particulates) to comply with the needs of the DOE sites.

INTRODUCTION

Since the establishment of the French Atomic Energy Commission (CEA) Saclay nuclear center in the 1950's, liquid radioactive wastes from different facilities within the boundaries of the center have been transported to the site's liquid processing plants using specially designed tanker vehicles. As part of the development of nuclear activities in France, the shipment of radioactive liquids between different sites throughout the country became necessary. Based upon the experience acquired at the CEA nuclear centers, four models of tanker trailers, compliant with the French and European regulations for off-site transportation of radioactive liquids have been developed by the CEA. The main trailers, which are frequently used for transportation in France and also in other European countries, are the following:

The LR54 trailer is equipped with an unshielded tank with a usable capacity of 19.5 cubic meters. It is an industrial package designed for the transportation of low activity liquids (less than 10-5 x A2 per gram of specific activity, and 100 x A2 for the total activity, Ref. 1). Three units have been in service in France since 1985.

Note: A2 is an activity limit defined in Ref. 1 and 2 which depends upon the nature of each of the radionuclides (e.g. A2 limit is equal to 0.5 TBq for Csl37).

The LR56 system is a trailer equipped with a 50 mm equivalent lead shielded cask with a 4 cubic meter usable capacity. It is a type B (U) package (1, 2) designed for the transportation of medium to high level activity liquid. The cask model has obtained the certification as a type B(U) container by the French safety authorities. One unit has been in operation in France since 1988, a second unit since 1993.

The LR44 is a trailer equipped with a 150 mm equivalent lead shielded cask with 1.3 cubic meters usable capacity. It is a type B (U) package (1,2) designed to allow transportation of high level activity liquids using more shielding than for the LR56. The cask model has obtained the certification as a type B(U) container by the French safety authorities. One unit has been in operation in France since 1978. The LR40 is a trailer equipped with a 30 mm equivalent lead shielded cask with 2.8

cubic meters usable capacity. It is a type B (U) package (1) designed for the transportation of medium activity liquid. The cask model has obtained the certification as a type B(U) container by the French safety authorities. One unit has been in operation in France since 1980.

The present paper focuses on the LR56 liquid transportation system, which was recently selected by the Hanford and the Oak Ridge U.S. Department of Energy (DOE) sites for transportation of radioactive liquids. The paper presents the new applications and provides technical details regarding the modifications that have been made to the system in order to comply with the type of waste to be transferred.

THE BASIC LR56 SYSTEM

The LR56 assembly (see general outline of the LR56 system presented in Fig. 1) is composed of the liquid transportation cask itself mounted on a road trailer with additional peripheral equipment. Liquid transfer operations can be performed and monitored without external assistance using trailer mounted ancillary systems such as: a hydraulic arm to handle the cask plugs, a nitrogen supply station to purge the tank from eventual hydrogen build up due to radiolysis, an air filtration and vacuum/compressed air production cabin and utilities, and a control and monitoring cabin. Vacuum/compressed air and pressurized oil to operate the crane are supplied through pumps actuated by an on-board combustion engine. Only the cask itself is type B(U) certified; it is sealed and disconnected from all the peripheral equipment in the transport configuration.

Fig. 1

Cask

The cask consists of a horizontal cylindrical confinement tank surrounded by several layers of containment, mechanical, biological and thermal protections. The final external dimensions of the cask are 3.7 meters long by 2.15 meters in diameter. The currently approved maximum weight is 23,100 kg.

Confinement Vessel

The confinement vessel seals the waste from the environment. It is made of stainless steel type Z1 NCDU 25.20(or B 625 UNS 08-404 under ASTM code), highly polyvalent steel for use with aggressive chemicals, in particular phosphoric, sulfuric and hydrochloric acids. The vessel is cylindrical with plate thickness of 8 to 10 mm and rounded heads. The interior of the vessel has two baffle plates and supports for level indicators, transfer pipes and sampling pipes. Operating equipment such as valves, level measurement sensors and samplers enter through three wells on the upper longitudinal axis of the vessel. The wells are closed with bolted lids equipped with double O-ring seals which ensure the continuity of the first confinement envelope. The pressure between the two seals is monitored to check for tightness before and after transportation.

The following equipment is flanged to the well's base plates and is removable for maintenance:

Rear Well: Two special self-sealing stainless steel connectors are used to connect the loading or the unloading hoses to the tank. These connectors are derived from a standard design used for commercial airline refueling and provide a high degree of safety with minimum retention of contaminated liquids. Two separate mechanical devices ensure the latching of the connector on its base and the opening of the internal sealing valves. The two actions are mechanically interlocked. The connector bases

are mounted on hand valves to isolate the tank content during transportation. A liquid sampling connection is connected to a liquid sampling tube ending near the bottom of the tank.

Central Well: The central well is equipped with the level measurement sensors: a float driven very high level switch, a low level float driven switch and a float driven continuous level measurement system activating a resistive line.

Front well: The front well (with respect to the direction of motion of the trailer) is equipped with the cask venting connection, the hydrogen gas sampling connection and a redundant very high level float driven sensor

Containment Vessel

The containment vessel is made of a 6 mm 316L stainless steel, offset 20 mm from the confinement vessel by spacer tubes. It protects the other components from any liquid spills. A drain tube is placed in the intervessel space to check for liquid presence and drain it.

Biological Shield

35 mm of soft lead is placed around the containment vessel. The continuity of the biological shield around the access wells is ensured by two means. First, 35 mm plates of lead are cast in stainless steel crows welded inside the confinement vessel around the well base plates. Second, removable lead bricks are bolted on the top of the base plates and placed around the penetrations. The mechanical protection envelope (described below) provides additional biological shielding leading to a total of 50 mm lead equivalent shielding.

Mechanical Protection

The lead shield is surrounded by a thick carbon steel vessel (30 mm A42FP) providing the mechanical protection of the cask in the drop test conditions. Continuity of the mechanical envelope at the access well openings is provided by three heavy plugs. These plugs also ensure the closure of the secondary containment vessel.

Thermal Protection

A non-centered shell of 150 mm to 550 mm balsa and redwood provides thermal protection of the tank against external fires. It also provides for mechanical shock absorption in case of external impacts or drop. The continuity of the wood envelope is also ensured inside the removable plugs.

External Envelope

A 6 mm painted carbon steel layer provides final weather protection of the assembly.

Cask Securement

The cask lies horizontally on cradles which are welded to the trailer frame. The cask is immobilized by shackles bolted onto the cradles and lengthwise by stops built into the front of the trailer and rear of the rear cradle.

Trailer

The total length of the French version of the trailer is 9.37 meters (31 feet), width is 2.45 meters and height 4 meters. The fully loaded gross weight is 32 metric tons without the tractor

IAEA Certification Tests

Tests have been performed on a 1/3 scale mock-up demonstrating the tightness of the cask after the regulatory 9 meters drop test and 1 meter penetration drop test on a 15 cm rigid rod. Behavior under the fire,

immersion and other regulatory conditions has been demonstrated by calculations.

Main Characteristics of the Content

The reference cask model has been certified for the transportation of liquids with the following general specifications:

Activity limits:

The IAEA regulatory limit (1) imposes a maximum of 0.1 mSv/hour radiation field at 1 meter from the cask, which leads to the following activity limits:

< 10.7 x 1011 becquerels/cubic meter (29 Ci/m3) for gamma emitters at less than 0.8 MeV

< 8.14 x 1010 becquerels/cubic meter (2.2 Ci/m3) for gamma emitters at less than 1.3 MeV

If the total activity is larger than 3 x 103 A2 or 1.11 x 103 TBq (3 x 104 Ci), special notice must be made to the French authorities.

Maximum concentrations:

nitric acid: 30%, 5.5N

sulfuric acid: 50/O, 7N

CL- anions: 1 g/l

F- anions: 0.1 g/l

Maximum plutonium content: 200 g

Thermal power

10 W (derived from the fissile content)

Maximum operating effective pressure:

3 bar (3 x 105 Pa), the confinement vessel is pressure tested at 4.5 bar and helium leak tested.

HANFORD SITE APPLICATION

The US DOE Hanford site has operated since 1943 with the primary purpose of plutonium production (3). The liquid waste from the plutonium chemical separation process has been stored in large underground tanks (the "tank farms") for future retrieval, treatment and final disposal. The forms of waste include various mixtures of sludge, liquid, salt cake, or slurry. The waste is alkaline; principal radionuclides include uranium, uranium fission products and fission decay products. Approximately 46 single-shell tanks at the Hanford site contain interstitial and supernatant liquids which may leak from the tanks, due to the age of the tanks. Typically, pumping via pipeline to other tanks is utilized whenever such leakage is detected. However, various conditions may preclude such transfers taking place, thus the need for a flexible mobile above-ground auxiliary transfer system arose. Such a system must meet DOE approved on-site packaging standards for type B quantities of high-level radioactive materials.

At the present time, no domestic DOE or NRC type B packaging with the appropriate level of shielding is available in the United States for transport of radioactive liquids in bulk volumes (i.e. greater than 1 liter volume). It was decided that the best way to meet the tank farms' needs was to select an existing and proven type B packaging, the LR 56 cask system used in France.

This system is currently being purchased by Westinghouse Hanford Company (WHC) from Numatec, Inc. (a Cogema Inc./SGN company) under license from the CEA. The system was delivered to the site in late 1995.

OAK RIDGE SITE APPLICATION

The US DOE Oak Ridge National Laboratory (ORNL) is in the process of upgrading the liquid low-level radioactive waste-generator collection

facilities, transfer systems, treatment facilities, and interim storage facilities on site to meet regulatory requirements. Existing single-wall tanks are either being replaced with doubly-contained tanks or removed from service. Single-wall piping systems are either being replaced with doubly-contained piping systems or are being removed from service and the radioactive waste is being transported to the central waste collection system.

The current transportation of liquid radioactive waste at ORNL uses a tanker truck which is not shielded and does not meet the requirements of the US Department of Transportation (DOT). In addition to transporting waste from the waste generators on the ORNL site, a DOT Type A package transporter will be capable of transporting liquid radioactive waste via public highways from other local US DOE sites not contiguous with the ORNL.

In 1992, the operator of the US DOE Oak Ridge National Laboratory, Martin Marietta Energy Systems (MMES), initiated an evaluation of potential suppliers of a liquid low-level radioactive waste transporter with a capacity of approximately 1000 gallons. MMES action based upon this initial evaluation was deferred due to funding priorities. In early 1994, funding was made available and the evaluation was re-initiated. Independent of the WHC assessment of available liquid radioactive waste packages, MMES determined that the procurement of an existing Type B package (the LR56) was advantageous because of the time and expense involved in initial design and testing of a DOT Type A container. Subsequently, MMES entered into a teaming agreement with WHC (which had by this time initiated procurement activities with Numatec, Inc) for WHC to perform the procurement activities for a second unit to be supplied for the Oak Ridge site. Under such a teaming arrangement, the two US DOE site operators were able to share resources in reviewing design modifications, performing witness points, and contract administration. This second system purchased by WHC will be delivered to the Oak Ridge site in early 1996.

EVOLUTION OF THE LR56 BASIC DESIGN

In order to meet the Hanford and Oak Ridge sites' requirements, some modifications of the basic LR56 system have been made. The main modification is the addition of a rinsing system inside the compartments of the confinement vessel to handle the presence of sludge and insoluble particles in the liquids to be transferred. The modifications are described hereafter; the Oak Ridge version contains only the ones marked by an asterisk.

Rinsing/Spray-wash (*)

Each compartment of the confinement vessel is equipped with one or two rotary spray wash nozzles to facilitate the wash down of solids towards the sump. Fixed nozzles are also installed to improve the cleaning of critical areas such as the level measurement floats. The water supply pressure is 60 to 90 psig. To allow for replacement of the spray nozzles, the base plates of the wells have been made removable with the penetrations welded on the flange.

This modification does not affect the confinement barrier (closed at the lid level) and provides additional flexibility to the system. Moreover, the removable lead brick protections initially placed in the wells have been replaced by permanent shielding plates cast in additional welded enclosures placed inside the confinement vessel. This clears the space around the penetrations and simplifies the maintenance operations.

Temperature Sensors

In order to provide for the ability to monitor the temperature inside the liquid and the sludge at various levels, five thermocouples have been installed in the tank. One thermocouple is placed in a guide tube in the intervessel space between the confinement and the containment vessel to measure the bottom tank temperature. Four additional sensors are placed in a tube fixed on a well base plate to measure temperature at various levels. The upper level sensor positioning corresponds to the maximum high level of liquid in the tank.

Redundant Level Measurement

A capacitive continuous level measurement probe is installed in the central well. It is not directly used in the control logic but provides redundant information using a different technology than the primary system, using a float driven technology.

Annulus Leak Detection

In order to permanently check for the presence of liquid in the intervessel space, a resistive probe is placed in a guide tube down to the bottom sump. The information is sent back to the monitoring station and processed in the safety logic of the automatic controller.

Neutron Measurement

A 15 mm inner diameter tube is placed in the lower protective wood layer, in contact with the carbon steel mechanical protection envelope. It is intended to be used as a guide for the insertion of a neutron detection foil in order to detect the presence of any sedimented fissile material.

ASME Filtering (*)

The cask vented air filtering station has been redesigned to comply with the ASME 509 and 510 requirements. The HEPA and active coal filter efficiencies are now testable in situ. The new design also allows in-situ replacement of the filters under bag transfer without dismounting the filter housing.

Electrical Motors (*)

The on-board combustion engine (e.g., used for the vacuum/pressure pump and the pressurized oil for the crane) has been replaced by electric motors supplied by an external source of 460 V AC current. The system is less autonomous than the French version but gains in flexibility, decreased pollution for indoor operations and noise.

PLC Control System (*)

The control system, initially relay driven, has been replaced by a Programmable Logic Controller (PLC). New modes of operation have been added to take into account the rinsing operations and the various loading and unloading configurations which are specific to the U.S. applications. The PLC allows the exchange of monitoring and permissive signals with the external loading/unloading stations in order to interlock the transfer operations. A remote control console is provided with the Hanford version allowing it to operate the system from a shielded area. The remote console is identical to the trailer console and is linked to the on-board PLC via a standard bus line.

US DOT Trailer (*)

The cask and ancillary equipment are mounted on a new trailer conforming to U.S. Department of Transportation (DOT) requirements. The total length of the trailer is 41 feet, which is significantly larger than the French version, due to differences between the European and U.S. road and highway transportation regulations.

Type B(U) Certifiability (*)

The Type B performance requirements of the French regulations are virtually equivalent to those of the United States, as they are ultimately based on the International Atomic Energy Agency (IAEA) Safety Series 6 (1) requirements used by both countries. However, an on-site SARP is still necessary because the French Certificate of Compliance for the LR56 is not recognized for domestic use in the United States. For off-site uses as a type B package, a licensing process will be pursued through the DOE or NRC, but such a license is not necessary for on-site use. The modifications made on the cask and the ancillaries have been designed in order not to affect the ability of the system to meet Type B(U) performance criteria. Analyses and calculations have been made by SGN in order to support this demonstration.

DOT 7A Compatibility (*)

To address the potential use on public access roads and highways between the ORNL site and nearby DOE facilities, an analysis of the LR56 system's compliance with the U.S. DOT 7A criteria has been conducted. As the system is already Type B certified in France, it easily meets the type A criteria. This has been confirmed by a systematic analysis. The volume of liquid waste to be transported under this certification will be operationally limited to meet the US DOT A2 quantity limits.

CONCLUSIONS

The LR56 system is a unique, well proven, and flexible Type B(U) liquid waste transportation cask. The equipment benefits from all the experience gained in the design and operation of liquid transportation casks in the French nuclear community, since the early 1950's (LR56 stands for "56's design of Radioactive Liquid Cask"). Two casks are presently in day-to-day use by the CEA. Since they were put into service, the LR56 systems have transported about 80 TBq (2100 CD of active liquids over a total distance of 35,000 km without any significant incident involving the hazardous material transported.

The two new systems that will soon be brought into operation on the U.S. DOE Hanford and Oak Ridge sites present new features which are broadening the spectrum of the LR56's applications.

ACKNOWLEDGMENTS

This paper presents work done by Numatec, Inc. under contract from Westinghouse Hanford Company. Numatec, Inc. (a Cogema/SGN U.S. company) has subcontracted to SGN, the nuclear engineering company in France. SGN is leading the engineering design, fabrication and commissioning of the system, working with SDMS, the main subcontractor already involved in the previous casks fabricated for the CEA. The authors also acknowledge Magali Ranchoux, Jean Michel Troude and Jean Louis Saulze of CEA liquid transportation departments, Guy Cordero of STMI and Didier Mercier of SDMS for their support in the development of the U.S. versions of the LR56 cask system.

ABSTRACT

Transuranic (TRU) wastes generated in Department of Energy (DOE) operations have, since 1970, been packaged to a large extent in unvented 55-gallon steel drums and have been stored with the intention of future retrieval. Today, there are safety concerns regarding these drums because of the potential presence of hydrogen and methane generated by radiolysis of hydrogenous wastes, and/or of traces of combustible Volatile Organic Compounds (VOCs) contained in the original waste materials. Any future handling and transportation of these waste packages must address these concerns. To provide a method for penetrating the drum and drum liner lids, sampling and analyzing the headspace gases, purging of undesirable gas mixtures, and installing an approved High Efficiency Particulate Air (HEPA) filter vent, a Drum Venting System (DVS) has been designed, built, and performance tested. The DVS has been shown to be capable of safely and effectively meeting all performance requirements in the venting of previously filled drums of TRU waste.

INTRODUCTION

Transuranic (TRU) wastes generated in U.S. Department of Energy (DOE) operations have, since 1970, been packaged to a large extent in unvented 55-gallon steel drums and have been stored with the intention of future retrieval. These wastes are intended to be disposed of permanently in the DOE Waste Isolation Pilot Plant (WIPP) facility. Today, there are safety concerns regarding these stored drums because of the potential presence of combustible headspace gases. Such gases can include hydrogen and methane resulting from the radiolytic decomposition of hydrogenous waste materials (e.g., paper, plastics, moisture) and/or from the presence of generally small amounts of combustible Volatile Organic Compounds (VOCs) that are cocontaminants of the TRU wastes. Any future handling and transportation of these waste packages must address this concern. Additionally, the WIPP Waste Acceptance Criteria require all packages to be vented, and that all such packages shipped to WIPP in the DOE TRUPACT-II Type B container must be both vented and shown to meet combustible gas concentration limits. To provide a safe method for penetrating the drum lid and, if present, inner plastic liner lid, sampling and analyzing the headspace gases,and installing an approved filter vent, NFT Incorporated (NFT) has developed a Drum Venting System (DVS) for the remote performance of these functions. This paper discusses the design, operation, and performance testing of the DVS.

SYSTEM DESIGN

The NFT DVS, as depicted in Fig. 1 and 2, is a stand-alone, skid-mounted system, requiring only external electrical power. The DVS is capable of properly installing an approved filter vent in a previously filled drum of TRU waste. In this process, a sample of headspace gas is collected and analyzed. In the event of a flammable headspace gas mixture being detected, the system can purge the gases present. The DVS is comprised of

several components and subassemblies, including the powerhead subassembly, glovebox, drum cabinet, gas analysis system, air filtration system, and remote controller assembly. Each of these is described below.
Powerhead Subassembly. The electrically powered powerhead subassembly is the key mechanical subassembly within the DVS. It contains a structural frame that supports and stabilizes a linear drive and a nutrunner.
Linear Drive. A stepper motor-driven, screw type linear drive controls the vertical movements of the powerhead assembly. The DVS employs a linear drive controller which precisely controls the movements of the powerhead assembly. The controller can store up to 100 unique and predetermined linear motion sequences or programs.
Nutrunner. The DC-motor driven nutrunner is mounted to the powerhead frame and provides the rotary motion to a socket attachment that holds the head of the filter assembly during the piercing and insertion operations. This nutrunner is a variable-speed unit capable of operating at higher speeds when piercing the lid and slower speeds when installing the filter. The nutrunner functions as the torque source which enables the filter threads to cut into the drum lid such that the filter seats securely in the drum lid. The nutrunner controller is a microprocessor-based, programmable, rotary motion controller. The controller can store up to 64 unique and predetermined rotary motion sequences or programs.
Glovebox. The glovebox that contains the Powerhead Assembly was designed and fabricated in accordance with the American Glovebox Society's "Guidelines for Gloveboxes", AGS-G001-1994. An inlet filter housing contains one 8x8 inch gasket seal High Efficiency Particulate Air (HEPA) filter element. A small airlock (approximately 10x10x10 inch) is provided to permit entry of drum filters and other small components, as needed.
All electrical components within the DVS glovebox comply with National Electrical Code standards in that they are intrinsically safe (nonsparking), or are of a "purge" design which prevents ignitable gases from entering their interior spaces where electrical discharges may be present. For example, the linear drive motor has a constant flow of air to prohibit any contact with ignitable gases which could possibly be present in the glovebox. The nutrunner, on the other hand, is nonsparking in design.
Fig. 1
Fig. 2
Drum Cabinet. The drum cabinet is a rectangular heavy steel box structure designed to enclose a 55-gallon waste drum, or an 83-gallon overpack drum, and of sufficient size as to dissipate the pressure from a worst case headspace gas ignition (drum pressurization to 136 psig) to <15 psig. The glovebox is attached to the top of the cabinet, with a common mounting plate used to seal the top of the cabinet and bottom of the glovebox. Following fabrication, the cabinet was successfully pressure tested to 22.5 psig.
The cabinet design includes a 24x24 inch fluid seal HEPA filter housing for inlet air. A backflow prevention device is present in the cabinet to minimize the probability of filter failure in the case of overpressurization. Two doors are present. One is a small access door used primarily to inspect the top surface of the drum for contaminants prior to opening the large, drum access door. Both doors are gasketed to provide a tight seal during both normal operating conditions and abnormal events. Both doors have sensors to tell the operator of their open or closed status.

The drum lift and weighing subassembly is contained within the cabinet. The major components include a pneumatically - operated air-lift, (air stroke actuator) and force transducers. Two force transducers (weight load cells) are used with the lifting mechanism to provide downward force information. Following placement of the drum in the cabinet, the lifting device is raised slightly to permit weighing of the total mass lifted, from which drum weight is determined. The drum then is lifted to seal against the drum lid seal, thus isolating the cabinet from the above glovebox. By adding a predetermined sealing force to the total weight, the total upward lift force required for this operation is determined.

Gas Analysis System. The headspace gas analysis system utilizes a Varian Model 3400 CX gas chromatograph (GC) tuned and calibrated to quantify hydrogen, methane, and a selection of VOCs. The dual column system uses a Flame Ionization Detector (FID) to detect the VOCs, and a Thermal Conductivity Detector (TCD) to detect hydrogen and methane. The system collects a real-time sample of drum headspace gas, and within approximately 5 minutes, prints out the gas concentration results. A personal computer (PC) software package fully automates the analysis and quantitation of the headspace gas results. The system alarms if any gas concentration exceeds the preset levels.

Air Filtration System. The air filtration system is responsible for ensuring that any radioactive contaminants released from a waste drum by any mechanism within the DVS are fully contained within the system. During operation, constant negative differential pressure is maintained within the drum containment cabinet and glovebox. The exhaust fan is an induced draft type, which is rated at 1,000 CFM maximum. The fan is equipped with a variable speed controller to permit the adjustment air velocity, and hence the pressure differential within the cabinet and glovebox. Parallel ductwork connects the outlets of the glovebox and cabinet to the common filter train. In the outlet from the glovebox, an adjustable damper is present to allow adjustment of the airflow. Adjacent to the damper is a backflow device that prevents overpressure within the cabinet from backing up into the glovebox. The filter train consists of one roughing filter and two HEPA grade filters, all in series.

Remote Controller Assembly. An Industrial Process Controller (IPC) is the key interface between the machine and the operating personnel. The IPC is connected to a special touch-screen interface that allows the operator to control the course of action during the drum-venting process. For example, the linear drive controller and the nutrunner controller are electronically connected to the IPC, which issues discrete logic signals that cause the execution of predetermined motion sequences or programs. The IPC software prompts the operator for input via the touch-screen user interface. The resident software provides a flowchart-oriented operational basis for operation of the system (an operation is completed before the next operation in the sequence is begun). The entire control and data station is enclosed in an electrical cabinet affording both personnel and equipment protection during the operation.

DRUM FILTER ASSEMBLY

The filter used normally in the drum-venting operation is pictured in Fig. 3. A short-stem version, used in the event an impenetrable object is encountered, is also shown in Fig. 3. The normal filter has a self-boring, self-tapping stem. The drill-type tip of this filter is made of hardened tool steel (high-speed steel). The housings of both units, which are otherwise identical, are fabricated of 316 stainless steel. The

filter media is a carbon-bonded-carbon material and is performance tested to provide >99.97% removal of 0.3m to 0.7m particles. The air delivery capacity of the filter is 200 ml/minute at 1 inch of water column.

OPERATIONAL SEQUENCE

The following is a description of the operational sequence upon which the DVS design and programming of IPC software is based.

Power Up. All DVS subsystems operate on 125 VAC power, except the air handling train which is 240 VAC, three phase. System power is initiated manually.

Fig. 3

Change Operating Parameters. After powering up, the IPC displays currently set system process parameters which a qualified operator, by means of a password, can adjust if needed based upon prior knowledge of the drums to be processed.

Insert Filter In Socket. In preparation for DVS operation, the operator manually, through the glovebox gloves, places a filter into the specially designed, close-tolerance fitting, slotted round-head recess in the socket.

Drum Load. The operator opens the drum cabinet door and places the bridge platform in the recess to secure the door in the fully opened position. This allows the drum and dolly to be loaded into the cabinet and prevents the door from closing prematurely. The operator then removes the bridge platform and secures the door.

System Initialization. The IPC directs the HEPA blower to start up and reach its setpoint speed.

Drum Weigh. The IPC initiates a flow of pressurized air into the air stroke actuator. As the actuator slowly inflates, the drum is lifted until the beam of a photoelectric sensor is broken. This indicates the drum is sufficiently raised to be weighed by the force transducers.

Drum Lift. Upon receiving a signal from the operator, the IPC reinitiates the flow of air to the actuator which lifts the drum further to where the lid is pressed against the molded rubber seal of the seal assembly in the cabinet ceiling with the appropriate lift force, as measured by the force transducers.

Form Vacuum Chamber. Upon achieving the appropriate lift force, the operator initiates a signal causing the powerhead socket to descend into the seal assembly cavity. As this occurs, a vacuum pump begins to evacuate the now sealed chamber.

Seal Test. With the chamber formed and evacuated, the DVS tests the integrity of the chamber by monitoring any in-leakage of air. If the reduced pressure in the chamber is seen to increase by less than a predetermined amount over a short period of time, an adequate chamber seal has been achieved. If an adequate chamber seal is not achieved, the operator can either retry to form the chamber or proceed to the next step, noting that the headspace gas analysis results may be compromised by outside air.

Bore to Sample Depth. Upon receiving a signal to proceed, the nutrunner is caused to descend and rotate at "boring speed." In this operation the drum lid first is penetrated, and subsequently the liner lid is penetrated. However, the self-tapping threads of the filter assembly have not yet engaged with the drum lid. At this point, all downward and rotational motion of the filter ceases. As soon as the drum lid is penetrated, headspace gas fills the small evacuated chamber created above.

Sample Analysis. The hollow stem and access stem holes of the filter allow flow of headspace gases into the sealed chamber. The operator now initiates the gas sampling and analysis operation of the GC. Here, headspace gas is slowly pumped from the drum, through the small chamber, to the GC. Upon completion of the gas sampling and analysis, the PC displays the analytical results.

Headspace Gas Purge. When an undesirable concentration of combustible gas is measured, an evacuate/purge cycle is initiated. Here, the drum headspace gas is partially evacuated, followed by refilling with dry nitrogen. This cycle can be repeated as needed to reduce the combustible gas concentration. Subsequently, the headspace gas is resampled and analyzed for verification that the drum is safe to handle.

Install Filter. Following completion of an analysis showing acceptable headspace gas concentrations, the operator initiates the filter installation process. The IPC synchronizes the nutrunner controller and the linear drive controller to operate at the optimum thread speed and feed (descent) rate, based on the filter's thread characteristics. Using the nutrunner's torque transducer output, the IPC slowly lowers the powerhead socket until the torque transducer output indicates the threading operation is in progress. Rotary and downward motion continues until the torque transducer output achieves the predetermined setting of 18 ft-lbs, thus indicating that the filter is properly installed and seated.

Impenetrable Object. If an impenetrable object is detected at any point in the boring or filter installation process, such an indication will immediately stop all powerhead motion, with the IPC indicating the status to the operator. Should this occur during the boring operation, the subsequent gas sampling/analysis and evacuate/purge (if needed) cycles will be completed before any corrective action. Following the operational stoppage (and the continuation of operations, as appropriate), the operator can direct the powerhead assembly to retract the filter into the glovebox. At this point, the long-stem filter is replaced with a short-stem filter (see Fig. 3), which then is installed in the normal manner.

Lower and Unload Drum. Following completion of the filter installation, the operator lowers the drum in the drum cabinet. At this point, the operator opens the small access door and can check the drum lid near the filter for radioactive contamination. If any is found, the drum lid can be wiped clean to a level acceptable for removing the drum from the cabinet. The drum then can be removed from the cabinet through a reversal of the "drum load" step, and another drum subsequently can be loaded.

PERFORMANCE TESTING AND RESULTS

The DVS Test Plan was developed and accomplished to demonstrate the overall abilities of the system. Specific tests included the following:

- Ability to penetrate a "normal" drum lid and install a filter assembly. Testing included leak tightness and torque verification.
- Testing as above on drum lids containing "irregularities" such as a rusted surface or minor denting.
- Ability for system detection and recovery from an impenetrable object.
- Ability to purge the headspace volume with an inert gas.
- Ability to measure the weight of a drum, determine the required lifting force, and apply that force.
- Ability to perform representative headspace gas sample acquisition and analysis.

Normal Drum Lid and Liner Penetration/Filter to Drum Lid Seal

Testing was performed by installing filter assemblies, in the normal operational sequence, into lids of 55-gallon drums. Each drum contained a 90-mil high density polyethylene (HDPE) liner. Following the installation, each assembly was visually inspected to verify the required penetration of both the drum and liner lids, and the apparent proper installation of the filter. To verify a leak tight seal between the filter housing and drum lids, each assembly was tested utilizing Dioctyl Phthalate (DOP). Here, a dual chamber assembly was used to seal both sides of the lid around the filter for application of the DOP testing to ensure that DOP particle leakage through the assembly met testing requirements for HEPA grade. A calibrated torque wrench was used to measure the torque for the filter installations.

A total of thirty five HEPA grade filter vents were installed by the DVS in full operational mode into "normal" drum lids. Subsequently, each was visually inspected and shown to have properly penetrated both the drum and liner lids. Of these, 34 passed the DOP HEPA testing standard of a minimum 200 ml/minute flow rate and less than 0.030% penetration of DOP aerosol at one inch of water pressure. The one assembly not passing was found to be properly installed, and had DOP penetration of 0.6%. Disassembly and examination of the gasket indicated that a few cutting chips had not been properly blown out of the way and had lodged under the gasket. The installation torque measured in these tests was 18 + 0.4 ft-lbs.

Irregular Drum Lid and Liner Penetration/Filter to Drum Lid Seal

Testing was conducted exactly as described above. Here, a total of eleven filter vents were installed. Of these, ten subsequently passed all tests, with the self-tapping threads of one filter "stripping out" the hole in the drum lid. Subsequent investigation showed the lid area in which the filter was installed to be "slick", resulting from a possible oil-like residue. Stripout in this one instance occurred because of the reduced friction between the neoprene gasket and drum lid, thus not permitting the DVS to achieve the target torque of 18 ft-lbs. Threading in this case continued until the drum lid sheet metal stripped out. As a result of this testing, it was recommended that (1) drum lids be inspected to ensure that wet, oily, or otherwise slick surfaces not be chosen for filter insertion locations, and (2) all installed filters should be secondarily sealed with a fillet of silicon adhesive between the drum lid and filter head side wall.

Detection and Recovery from Impenetrable Object

In this test, a metal impenetrable obstruction was placed within 1/2 inch of the drum lid. The resistance measured on the powerhead controls was the measure of the force exerted on the object. Here, the DVS attempted to install a filter in the drum lid, where the lid was positioned such that the filter would encounter the steel object below the lid. Following the encounter with the "impenetrable object", the DVS would need to recover the original long-stem filter and install a short-stem filter in the hole in the drum lid.

In each replication of the test, the installation of the long-stem filter was stopped automatically by the excessive force caused by encountering the impenetrable object. The operator then was able to sequence the DVS operation through the subsequent retrieval of the long-stem filter, replace this filter with a short-stem filter, and properly install the short-stem filter in the drum lid.

System Purge

In this test, the DVS programming was tested to demonstrate the ability to remove and replace an undesirable headspace gas mixture. Following the penetration of a drum lid and sample analysis, the system demonstrated the ability to evacuate the drum headspace repeatedly to 11 psia followed by the purge cycle of refilling the drum headspace with nitrogen back to normal atmospheric pressure (14.7 psia)

Weigh Drum/Determine Required Lifting Force

Six drums of differing weights were tested, with a "seal force" of 200 lbs set for the test. Total measured lift force (drum weight plus seal force) varied by a maximum of + 3 lbs from the expected calculated value in each case, thus indicating an acceptable air-tight seal was achieved between the drum lid and seal gasket.

Headspace Gas Sample Acquisition and Analysis

Testing in this case was dependent on the ability of the system to establish and maintain a good seal between the seal plate gasket and drum lid (see above test), and on the proper calibration, function, and complete variance analysis of the GC sampling system. In this test, a sample drum was placed in the DVS and was lifted to seal against the seal gasket. The proper seal lift force first was verified. Following the lowering of the socket assembly to form the vacuum chamber, a vacuum was drawn and the chamber then isolated for one minute. The vacuum pressure decay within the chamber then was measured to verify the establishment of acceptable seals. Finally, the drum lid used in these tests had a reservoir attached containing a sample gas. One sample of this gas mixture was withdrawn using an injection syringe for direct injection into the GC. Subsequently, a filter assembly penetrated the drum lid in a normal DVS operation, thus allowing a simulated headspace gas sample to be obtained and analyzed. All analyses were repeated three times.

In the testing accomplished, twenty replications of measurements of total lift force showed a variation of + 2.3%. Vacuum pressure decay during the one minute hold time was negligible, well within the 5% reduction acceptance criteria, in all cases. Test acceptance criteria for the analysis of hydrogen, methane, and total combustible VOCs in these tests was to have no greater than a 25% deviation from the injected constituents of the calibration gases. The calculated Relative Percent Differences of the mean of the simulated headspace gas concentrations versus the mean of the actual (injected) concentrations for hydrogen, methane, and VOCs were <5%, < 5%, and < 10%, respectively.

SUMMARY

Trial and performance testing operations of the DVS have shown a normal cycle time of approximately 25 minutes/drum, with an increase of this time to approximately 45 minutes/drum if the evacuate/purge and resampling steps are mandated. The extensive testing of the DVS has demonstrated the accomplishment of all system performance objectives, including:

- Safe and efficient filter installation in a manner to ensure leak tightness of the filter seal to the drum lid;
- Reproducible and representative sampling of headspace gases; and
- Effective purging of unsafe levels of headspace gases, when necessary.

All other operational objectives of the DVS also have been demonstrated. The NFT DVS has been shown to provide a safe and effective method for venting previously filled drums of TRU waste.

USE OF GRAFTED MACROCYCLES IN THE TREATMENT OF ALPHA CONTAMINATED LIQUID WASTES

H. CHOLLET
Commissariat l'Energie Atomique (C.E.A.)
Centre d'Etudes de Valduc
21120 Is Sur Tille, FRANCE

ABSTRACT

The high selectivity and strong coordination of polyazacycloalkanes with transition-metal ions have been well established and make these ligands ideal candidates for use as reagents in performing metal ion separations. One way to achieve this aim is the covalent bonding of these macrocyclic ligands to a solid support. Indeed, during the last decades, numerous researches have been devoted to the surface modification of various supports used in dioxygen transport, waste-water treatment, metal-ion chromatography or recovery of trace-metal ions. The solid support can be a synthetic organic polymer or an inorganic material. Silica gel has been selected in most applications. Macrocyclic ligand attachments to silica are relatively simple reactions, especially when compared to immobilizations involving organic polymers.

Our primary interest has been the study of free tetraazamacrocycles in the complexation of lanthanide- and actinide-ions and the X-ray determination of the configuration of their corresponding complexes. Obviously, this type of ligands offers new potential due in this field to the high stability of the formed complexes.

Our secondary interest has been the preparation of modified silica gel as a polymeric support for alpha waste-water treatment. The use of these macrocycles grafted to silica showed clearly the high efficiency of these materials to extract actinide traces contained in alpha liquid wastes.

INTRODUCTION

The "Centre du Commissariat l'Energie Atomique de Valduc" has launched for several years, a research program on the development of new macrocyclic ligands which are able to pull out actinides from industrial liquid wastes.

The continued interest and research for new macrocyclic ligands stems mainly from their use as models for protein-metal binding sites in biological systems 1), as selective complexants 2) of metallic ions, i.e therapeutic reagents for the treatment of the metal intoxication 3), radioactive waste water treatment 4), functional groups for chelating ion-exchange materials 5) and to study host-guest interactions. Tetraazamacrocycle ligands represent a class of macrocycles known for their ability to complex transition and non transition metal cations. The macrocyclic complexes of lanthanides are now currently used for other medical applications 6), radioimmunotherapy, contrast-enhancing agents in Magnetic Resonance Imaging (MRI), as NMR shift and relaxation reagents and in many other novel clinical techniques. The main target in molecule design is to synthesize macrocycles which are able to discriminate among the different metal cations.

One of the major problems in using macrocyclic ligands in such applications is the maintaining of the very expensive ligand in the water or organic phases. This makes their commercial use expensive, difficult to engineer, and a potential environmental hazard. One way to overcome these problems is the covalent bonding of the macrocyclic ligands to a solid support enhancing greatly at the same time their usefulness.

Our primary interest has been on the one hand, the synthesis of new tetraazamacrocyclic ligands in close alliance with Prof. R. Guilard Laboratory (Universit de Bourgogne) and on the other hand the study of their reactivity with lanthanide- and actinide-ions. Our second interest has been the macrocyclic ligand attachment on polymers for the recovery of ion-traces.

RESULTS AND DISCUSSION

The synthesis and characterization of new and original molecules have been carried out at the University. The DOTA and TETA compounds (cyclic tetraazatetraacetics acids) were prepared by reaction of the corresponding cyclic amines with chloroacetic acid in aqueous alkaline solution as described in the literature (4). A smooth and convenient one step synthesis of the other compounds is reported on Fig. 1. These ligands are synthesized by Michael addition of tetraazacycloalkanes to acrylic acid in absolute ethanol under reflux. All the compounds are obtained in a high yield (varying from 52 to 77%) after recrystallization in distilled water.

Fig. 1

The alpha emitters contained in Valduc Wastes are essentially plutonium-americium- and uranium-elements. In order to implement our extraction methodology, we have used respectively cerium and europium as models to plutonium- and americium-ions. The stability constants of the different metallo-macrocycles were determined from the potentiometric titrations using the "MICMAC" program (7). Therefore, these new macrocycles offer new potentialities due to the high stability of the formed complexes (pKM > 1020)

Table I

Moreover, their coordination is critically dependent on the nature of metallic ion and nitrogen substituents. Consequently, the determination of the conformation of these ligands is a key point.

The X-Ray structure of the DOTA/Gadolinium complex published by Dubost & al. (8) shows at the solid state a metal coordination at once by nitrogen and oxygen atoms. In this way, the metal-ion is encapsulated by the macrocyclic ligand (see Fig. 2a). On the contrary, a crystallographic study of the TETP/Cerium complex (9) exhibits at the solid state a very different coordination mode : in this case, the metal-ion is coordinated to the ligand only via oxygen atoms belonging to four different macrocyclic ligands (see Fig. 2b).

Fig. 2a,b

Whatever the coordination mode may be, the high stability of formed complexes prove the great potentialities of such molecules. Therefore, these results allow us to consider their use in alpha decontamination processes.

These macrocycles have been covalently bound to polymers (essentially Silica Gel) for using in solid-liquid extraction process. Macrocyclic ligand attachments on Silica are relatively simple reactions especially when compared to immobilizations involving organic polymers. Moreover, Silica Gel is a low-cost starting material and exhibits a good mechanical strength and swelling required for use, as an example, in high pressure liquid chromatography systems. For instance, macrocycles have been attached to Silica Gel by amide linkages (10) and by covalent carbon-silane bonds through a hydrosilylation process. Three different methods were used for capacity determinations (in complexed forms) : quantitative

E.S.R. measurements of copper (II) complexes, nitrogen, carbon and copper elemental determinations and UV-visible measurements.
Fig. 3
Industrial and synthetic solution decontaminations concerning uranyl nitrate have been realized specifically with a material (Si2323TrP : compound with Silica Gel). This compound is a cyclam (trisubstituted with propionate groups) attached by nitrogen linkage to Silica.
At a laboratory scale, synthetic effluent treatments show a complete decontamination of the treated effluent. In addition, successive extractions and elutions (using nitric acid) of uranium on Silica Gel or Si2323TrP prove the regeneration of these materials and consequently an easy recovery of the uranium-ions present in the effluents. Industrial solution decontaminations concerning plutonium- and americium-ions induce the same results (see Table II) : ion concentration < 5 Bq/m3 and equal to detection limits of analysis measurements.
On the basis of such results, the CEA has decided to build up a pilot facility to treat one part (1/10) of the annual effluent flow generated by Valduc Nuclear Center to confirm the preliminary study.
Table II
CONCLUSION
The tetraazamacrocycles offer large potentialities in various domains. The macrocyclic chemical research generate target molecules which are able to complex selectively a specific metal. Few ligands of this series, with appropriate geometry and substituents could permit the selective complexation of various metal ions and provide a real contribution in the protection of the environment.

Session 08 -- SAVANNAH RIVER SITE - PROGRESS IN WASTE MANAGEMENT AND ENVIRONMENTAL RESTORATION
Co-chairs: Lou Papouchado, WSRC
Rosemary Aldridge, USDOE
8-1
TECHNOLOGY IMPLEMENTATION AND CLEANUP PROGRESS AT SAVANNAH RIVER SITE
L.M. Papouchado
Westinghouse Savannah River Company
Savannah River Technology Center
Aiken, SC 29808
ABSTRACT
The integrated high level waste system at Savannah River was designed to convert 34 million gallons of liquid waste to glass and saltstone. Feed pretreatment and saltstone have started up and vitrification is scheduled

to start up in early 1996. New waste disposal vaults and startup of several other facilities such as the Consolidated Incinerator Facility and a mixed waste vitrification facility will help completion of the integrated system to treat and dispose of SRS wastes. Technology was utilized from industry, other laboratories, or was developed at the Savannah River Technology Center if it was not available. Many SRTC developments involved academia and other labs. SRS also has over 400 waste sites (400 acres) units in its characterization/remediation program. To date over 90 acres were remediated (23%) and by 1997 we plan to remediate 175 acres or 44%. Thirteen groundwater facility treatment sites will be in operation by 1997. SRS has provided and continues to provide unique test platforms for testing innovative remediation, characterization and monitoring technologies. We are currently testing DNAPL characterization and remediation and an in-situ Inorganic remediation technique for groundwater.

INTRODUCTION

The Savannah River Site (SRS) has operated since 1952 to produce Nuclear Materials for National Security. The site included five production reactors, two chemical separation plants, a fuel and target fabrication facility, and a tritium processing facility. For 35 years the site produced tritium and plutonium for the nuclear weapons stockpile. With the end of the Cold War, the site has increased its focus on waste treatment and environmental remediation to solve problems generated from decades of production. Supporting these operations and changing missions is an applied research and development laboratory - the Savannah River Technology Center (SRTC).

The Savannah River Technology Center's (SRTC) main mission has been to support site operations and, as a result, has developed a strong customer orientation and an understanding of site needs. Many of the processes and facilities that have operated at the site over the years, or that have recently started up, have been developed or enhanced by SRTC. In most cases, the development scientists and engineers participated from inception to startup. This has been one of the ingredients in the successful technology development approach used at the site. Utilizing integrated teams throughout the system life cycle to include all contributing groups - currently referred to as Integrated Product/Process Development Teams - has also helped. Another successful philosophy has been to couple small scale laboratory work with actual radioactive material with large scale or pilot facilities with simulated materials. We have found pilot scale testing to be invaluable for process and equipment development, process integration, materials evaluation, and finally, startup and troubleshooting of the actual plant. In several cases field demonstrations of the technology proved to be a critical element of the development cycle. Another principle has been to understand the fundamental science of the processes we operate and to retain that knowledge on site.

The legacy of this long period of nuclear materials production has resulted in over 34 million gallons of stored high level liquid waste (HLW), low level, hazardous, mixed, and transuranic solid wastes, and over 400 waste and groundwater units. In the early '80s, visionary site management pushed for and obtained support for the Defense Waste Processing Facility (DWPF) to treat the highest risk legacy waste - the stored high level liquid waste. This was followed by several other facilities to treat other waste streams and has now evolved to a detailed

and integrated Site Treatment Plan. A summary of the major waste streams, their treatment facilities and ultimate disposal is shown in Fig. 1. Many of the facilities are interconnected or depend on one another to provide an integrated approach to waste treatment.

Fig. 1

The integrated high level waste system at Savannah River was designed to convert 34 million gallons of liquid waste to glass and saltstone. Feed pretreatment and saltstone have started up and vitrification is scheduled to start up in early 1996. The system, shown in Fig. 2, consists of five separate but interconnected facilities (1). The waste sludge, which consists of metal hydroxides and oxides is first washed with water to reduce the alkali salts going to vitrification. Some batches will be washed with hot caustic first to reduce the aluminum content (reduce glass volume and viscosity). The first batch, Tank 51, has been washed and is ready to go to vitrification. The waste soluble salts will be treated in the "In-Tank Precipitation" facility. Sodium tetraphenyl borate is added to precipitate the major radioactive component, Cesium-137, and sodium titanate is added to sorb minor traces of strontium and plutonium. The slurry is then filtered by cross flow filtration. The resultant radioactive precipitate is sent to vitrification while the decontaminated salt solution is sent to "Saltstone" (grout) for treatment and vault disposal. The ITP facility started radioactive operation in September 1995 and has worked very well. A DF of 45,000 was obtained on the first batch, exceeding the target value of 1,500.

Fig. 2

In developing these pre treatment processes, pilot plant tests were run and combined with small scale tests on actual HLW to achieve a high degree of confidence. For ITP, a full scale plant demonstration was also performed which generated about 500,000 gallons of decontaminated salt solution.

The Saltstone plant was started up in 1990 and since startup has continually grouted the bottoms from the F/H Effluent Treatment Facility and the salt solution from the demonstration. With ITP in operation, the plant production rate will be greatly increased.

The DWPF vitrification plant has completed its waste qualification runs and is scheduled to receive its first radioactive sludge feed in early 1996. The cesium precipitate stream will be fed starting in mid 1996 when the entire integrated system will be in coupled operation. The vitrification process was extensively tested with an integrated pilot plant, multiple prototypes, and small scale processing in shielded cells with actual waste. Developers of the process are assisting in the startup and pilot plant engineers are working in the plant. The Saltstone process, on the other hand, was more conventional technology and was not piloted. It did require development in formulating the waste forms (2) and in conducting a performance assessment on the disposal vaults (3). The waste from (salt solution, cement, slag and flyash) and facility were designed such that groundwater from monitoring wells adjacent to the facility meets EPA drinking water standards. The facility is permitted as an industrial Waste Water Treatment Plant by South Carolina Department of Health and Environmental Control. Saltstone would be classified by the NRC as a Class A waste (least radioactive).

The F/H Effluent Treatment Facility was started up in 1987 and was designed to handle effluents (evaporator overheads) from the F and H areas (Separations and Waste Management) which were previously sent to

seepage basins. These low level liquid waste streams contain a wide range of inorganic and some organic contaminants. The process consists of reverse osmosis to remove 90% of the dissolved salts, mercury removal columns, and a polishing resin to remove residual Cs and Sr. The front end consists of a pH adjustment and filtration to remove solids followed by a carbon bed to remove organics. The concentrates are evaporated and the bottoms sent to Saltstone for disposal. This versatile cleanup system has board applicability at other sites. It has worked very well to meet NPDES discharge limits. It does not, however, remove any tritium contamination. The process was developed at SRTC and key steps in the process tested on a small scale with actual waste.

The Consolidated Incinerator Facility (CIF) was conceived as a versatile treatment for combustible liquid and solid wastes. It can handle low level, hazardous and mixed wastes. This 13 million BTU plant can burn 5.8M lbs solids/year and is a key facility in the SRS Site Treatment Plan. It consists of a rotary kiln, an afterburner and uses a wet scrubber system. Commercially available technologies were used in this project. SRTC did conduct pilot tests in areas of higher uncertainty such as the rotary kiln seals and the off-gas scrubbing system (4). The CIF is scheduled to destruct the benzene generated in DWPF from the hydrolysis of tetraphenyl borate salts. The ash and blowdown by products from the CIF will be immobilized in cement and disposed of on site in vaults. Hot operation is scheduled for early 1996.

For the disposal of low level waste, SRS has transitioned from direct disposal in trenches, to B-25 steel boxes in trenches, to B-25 boxes in vaults starting in 1994. The E-Area vaults are the first disposal system within DOE to have an approved performance assessment (5,6). We currently have vaults designed for low level, intermediate level, and tritiated wastes. A RCRA vault is planned as a future facility. Waste minimization is strongly emphasized on site. In addition, volume reduction using onsite compactors and offsite vendor treatment is receiving focused attention. The CIF will greatly contribute to volume reduction of the combustible waste as it comes on line.

For the numerous on-site streams of non-combustible, mixed waste, several treatments are being pursued for the most cost effective disposal. For example, one major stream, 6.5 x 106 gallons of waste sludge remaining from the metallurgical area operations, will be treated by a commercial vendor on-site. The novel contract is based on a fee per gallon of waste vitrified. SRTC assisted in the glass formulations to be used with the vendor's commercial melter/offgas system. This approach is applicable to other SRS mixed and low-level wastes and to the other DOE sites.

Transuranic (TRU) waste at SRS is stored on covered concrete pads while older TRU waste has been mounded over with earth. The site has 9.5 x 103m3 of TRU waste containing 5.75 x 105Ci. The high activity is due to the Pu-238 production operations at the site. The plan is to retrieve the waste and to repackage and characterize for shipment to WIPP. The site is also looking at OTD for treatment technologies for non-shippable material. This is a high priority need at SRS.

In summary, SRS has in place most of the facilities needed to treat and dispose of its wastes. Several key facilities have started up such that the whole integrated system is in operation.

Shifting over to the remediation side, SRS has over 400 waste units totaling approximately 400 acres which are in the characterization/remediation program. To date, 14 sites totaling 90 acres

(23%) have been remediated and by 1997, 23 sites will be closed totaling 175 acres or 44%. In addition, it is expected that a significant number will not need to be remediated after characterization is complete. The site has been aggressive in closing most of the major disposal basins. The basins adjoining the F and H Separations areas have been closed as has the Fuel and Target Fabrication (M) Area basin. In addition, a 58 acre mixed waste disposal site has been closed. The closures in all cases have consisted of a low permeability clay cap with drainage layers and a vegetative cover. The design of each closure was negotiated and approved by the state. With the basins, a sludge stabilizing step was included prior to capping. These have included grout, calcium carbonate stabilizer, and limestone/flyash additions. In the case of the mixed waste disposal site, dynamic compaction was performed to prevent future subsidence from damaging the clay caps. In this process, a 20 or 40 ton weight is repeatedly dropped on the surface using a crane.

Groundwater contamination at SRS consists principally of VOCs and radionuclide/metal contamination at several locations. Thirteen groundwater facility treatment sites will be in operation by 1997.

SRS was the location of the successful DOE-OTD Integrated Demonstration "Remediation of VOCs in Groundwater and Soils at Nonarid Sites." This demonstration, which has been extensively described, showed how to conduct successful collaborations between DOE laboratories, universities, industry and other government agencies. Integrated development and field deployment teams, using some of the best national resources, successfully demonstrated and later commercialized technologies and equipment that address characterization, monitoring and remediation of VOCs. Two notable remediation technologies were in-situ air stripping using horizontal wells, and in-situ bioremediation using methane and PHOSter injection (7). This well characterized site provides an ideal test platform and has received regulatory and stakeholder buy-in to test and implement innovative technologies. This experience has allowed SRS to develop several other test platforms to address different contaminants and environments. Extensive characterization and data sets are available as well as technical support and field analytical support for demonstrations or vitrification of technologies (8).

SRS is currently involved in several other demonstrations: Characterizing and remediating Dense Non-Aqueous Phase Liquids (DNAPLs), remediating metal ions contamination in groundwater, and testing innovative sanitary landfill remediation. Partnering with academia, industry and other labs has become a routine operating mode. This allows leveraging of DOE resources, utilizes the best available experts, and facilitates commercialization of new technologies.

Good progress is being made at SRS in Environmental Management because of visionary early planning, a bias for action and technology implementation, a needs-driven systems approach, and integrated process development teams.

THE DWPF: RESULTS OF FULL SCALE QUALIFICATION RUNS LEADING TO RADIOACTIVE OPERATIONS

Sharon L. Marra

Aiken, SC 29808

ABSTRACT

The Defense Waste Processing Facility (DWPF) at the Savannah River Site in Aiken, SC will immobilize high-level radioactive liquid waste, currently stored in underground carbon steel tanks, in borosilicate glass. The radioactive waste is pretreated and then combined with a borosilicate glass frit. This homogeneous slurry is fed to a Joule-heated melter that operates at 1150C. The glass is poured into stainless steel canisters for eventual disposal in a geologic repository. The DWPF canistered waste forms must comply with detailed waste acceptance specifications to be acceptable for eventual disposal.

The DWPF has completed Waste Qualification Runs which demonstrate the facility's ability to comply with the waste acceptance specifications. During the Waste Qualification Runs seventy-one canisters of simulated waste glass were produced in preparation for Radioactive Operations. These canisters of simulated waste glass were produced during five production campaigns of varying melter feed composition that also exercised the facility prior to beginning Radioactive Operations. The results of the Waste Qualification Runs are presented.

INTRODUCTION

Approximately 130 million liters of high-level radioactive waste, currently stored in underground carbon steel tanks at the Savannah River Site (SRS), will be immobilized in stable borosilicate glass in the Defense Waste Processing Facility (DWPF). The glass is poured into stainless steel canisters for eventual disposal in a geologic repository. To be acceptable for disposal the DWPF product (i.e. the canistered waste form) must comply with the Department of Energy Office of Environmental Management's Waste Acceptance Product Specifications (WAPS). (1)

The DWPF has recently completed the production of seventy-one canisters of simulated waste glass as part of it's Startup Test Program in preparation for Radioactive Operations. The Waste Qualification Runs portion of the DWPF Startup Test Program was designed to demonstrate that the DWPF could comply with the WAPS prior to the start of Radioactive Operations. Fifty-five of the seventy-one canisters of simulated waste glass were produced during these runs. Varying feed compositions were used to demonstrate that the DWPF could control the glass product over a range of materials using the DWPF Glass Product Control Program. (2) The simulated waste was transferred into the DWPF and processed using the same methods as for the radioactive waste. The glass and canistered waste forms produced during Waste QualificationRuns were extensively characterized. The results of this characterization demonstrate the DWPF's ability to comply with the WAPS.

PROCESS/PRODUCT OVERVIEW

The radioactive waste in the SRS Tank Farms has been separated into a water soluble salt solution and saltcake, and an insoluble sludge of metal hydroxides and oxides. The salt solution and saltcake are decontaminated for disposal as low-level radioactive waste by removing the radionuclides by precipitation and sorption. Sodium tetraphenyl borate is added to precipitate soluble salts of non-radioactive potassium and cesium. Sodium titanate is added to adsorb residual strontium and plutonium. The resulting slurry is filtered and the decontaminated filtrate is blended with cement, slag and flyash for disposal at SRS as a low-level radioactive waste. The slurry of the concentrated solids is transferred to DWPF for immobilization. The sludge portion of the waste is washed to remove soluble salts. If necessary, insoluble aluminum is removed through high temperature caustic dissolution. Thus, the radioactive waste from the SRS Tank Farms is transferred to the DWPF in two forms: precipitate slurry and sludge slurry. The waste is then processed and blended in the DWPF before it is vitrified, poured into canisters, sealed, and placed in interim storage. (3) See Fig. 1 for a schematic of the DWPF process.

The sludge is transferred directly into the Sludge Receipt and Adjustment Tank (SRAT) while the precipitate must first be processed in the DWPF Salt Process Cell to remove most of the organic material. The tetraphenyl borate compounds in the precipitate react in the presence of formic acid and copper (II) catalyst. The products of this reaction are aromatic organic compounds (benzene, phenol, and minor amounts of higher boiling aromatics) and an aqueous phase known as Precipitate Hydrolysis Aqueous (PHA). The PHA contains the cesium, soluble formate salts, boric acid and excess formic acid.

The sludge is neutralized with nitric acid in the SRAT. The PHA is then added to the sludge (at boiling). The excess formic acid in the PHA reduces the mercuric oxide in the sludge to elemental mercury. The elemental mercury is then steam stripped from the SRAT into a holding

tank from which it is later pumped and decontaminated. After the PHA and sludge are blended and processed in the SRAT, this SRAT product is transferred to the Slurry Mix Evaporator (SME) where a borosilicate glass frit is added and the slurry is concentrated to produce melter feed. The amount of sludge and PHA to be blended in the SRAT and the amount of SRAT material and frit to be blended in the SME is determined by the Product Composition Control System (PCCS). (4) The PCCS is a computer program that uses glass property models and statistical algorithms to develop blending strategies and to determine the acceptability of the melter feed before it is transferred to the melter. The PCCS uses lab analyses of tankcontents, tank volumes and existing tank heel volumes to determine an appropriate tank blending region. It chooses a target that minimizes the amount of frit to be added in the SME. However, any point in the acceptable blending region can be chosen by DWPF engineers as the blending target. PCCS is also used to predict SRAT and SME compositions based on existing tank compositions, tank transfers, and the uncertainties associated with sampling and processing. These predicted compositions for the SRAT and SME can be used to diagnose processing problems. This capability was used during Waste Qualification Runs as is described in a later section.

Fig. 1

The SME is the hold point in the process where feed acceptability is determined as part of the Glass Product Control Program (see below). The analyses of samples from the SME are used by the PCCS to determine the acceptability of the melter feed. The acceptability of the melter feed is determined using glass property models and statistical algorithms which take into account analytical uncertainty to ensure the glass product will be acceptable and that processing constraints (such as viscosity and liquidus) are met.

Once the melter feed material in the SME is determined to be acceptable, it is transferred to the Melter Feed Tank (MFT) and then fed to the joule heated melter. The DWPF melter has two pairs of electrodes. The feed slurry is introduced from the top of the melter and forms a crust, or cold cap, on the surface of the melt pool as the water is evaporated and removed via the off-gas system. The cold cap melts from the bottom and forms theborosilicate glass matrix. The nominal glass melt pool temperature is 1150C. The mixing behavior of the melter was evaluated during Waste Qualification Runs as described later. The glass is removed from the melter near the bottom through a riser and pour spout. A vacuum is drawn on the pour spout to pour the glass. A glass pour stream sample is taken occasionally during filling of a canister to confirm that the glass durability (as determined by the Product Consistency Test (5)) is acceptable. After a canister is filled, a temporary seal is installed to prevent free liquid from entering the canister during the decontamination process. Decontamination of the canister surface consists of blasting an air-injected frit slurry against the canister. The frit slurry from the decontamination process is used in the next SME batch as part of the required frit addition. The canister is then welded closed and transferred to an interim storage building. The DWPF canistered waste form contains approximately 1800 kg of glass. It is 300 cm in length and 61 cm in diameter.

WASTE ACCEPTANCE SPECIFICATIONS

To ensure that the DWPF product is acceptable for final disposal the Department of Energy Office of Environmental Management has developed the

Waste Acceptance Product Specifications (WAPS) (1) which the DWPF product (i.e. canistered waste form) must meet. These specifications are divided into five sections: waste form (borosilicate glass), canister, canistered waste form, quality assurance, and documentation. The most important of the glass specifications is the product consistency specification which states that the DWPF must control its process so that the glass produced is more durable than the DWPF Environmental Assessment glass (6) as measured by the Product Consistency Test (PCT). The PCT is a crushed glass durability test in which the results are expressed as the amount of boron, lithium, and sodium measured in the leachate. DWPF has developed a Glass Product Control Program (see below) to ensure that this specification is met. During Waste Qualification Runs, the DWPF demonstrated that it can comply with this specification as well as the other glass, canister, and canistered waste form requirements.

GLASS PRODUCT CONTROL PROGRAM

The DWPF has developed the Glass Product Control Program to ensure that the DWPF consistently produces a glass which satisfies the product consistency specification, and that there is demonstrable evidence that this has been achieved. In developing this strategy for producing an acceptable glass product, the DWPF has considered the following:

The only parameters which the DWPF can directly control that affect the results of the PCT are the chemical composition of the glass, and the uniformity of the feed to the melter. It has been shown in laboratory and large scale testing that chemical composition is the prime determinant of a glass's PCT results. (7)

It is not possible to recycle or rework glass which does not satisfy the specification in the current DWPF processingequipment.

DWPF waste glass is highly radioactive. Any testing to be performed for control or verification must be performed in shielded cells and, thus, must be simple and reliable.

The waste stream coming into the DWPF will vary. Thus, the program must be able to handle varying waste compositions.

The DWPF Glass Product Control Program ensures that the glass product satisfies the WAPS by controlling the composition of the melter feed. As described earlier, control of the melter feed is ensured by the hold point at the SME. No material is allowed to be transferred from the SME to the MFT until it has been determined to be acceptable. The PCCS is used by DWPF engineers to ensure that the SME material is acceptable. A glass property model that uses a thermodynamic hydration approach to represent composition is used to predict PCT results based on the SME composition. The free energy of hydration reaction for each glass component is multiplied by that component's mole fraction in the glass. These partial quantities are summed to represent the free energy of hydration of the glass. The free energy of hydration is related to the glass PCT results. The ability of the Glass Product Control Program to produce an acceptable glass product was demonstrated during the Waste Qualification Runs portion of the Startup Test Program.

STARTUP TEST PROGRAM

The DWPF Startup Test Program was modeled on the testing required for startup of a commercial nuclear reactor. The Startup Test Program:

Demonstrated the DWPF's ability to reliably produce an acceptable product that meets the requirements of the WAPS. This was accomplished during the Waste Qualification Runs portion of the Startup Test Program.

Demonstrated the operability, reliability, and integrity of the major process systems.

Provided operating experience to operations, maintenance, and engineering personnel.

Baselined equipment and system operating parameters.

Melter Startup

Prior to Waste Qualification Runs the melter was heated up and one melter campaign (FA-13) was performed. Two thousand pounds of startup frit were loaded into the melter. The startup frit was formulated to avoid corrosion and other problems during startup. The melter dome heaters were turned on to melt the top surface of the startup frit. Once the glass became molten enough to allow joule heating, the lower electrodes were energized. Once joule heating was established the first batch of melter feed material was fed into the melter until the normal melter level was reached. Once the melter glass level reached the upper electrodes they were energized. One canister was filled using the melter feed remaining from the batch used to fill the melter. Two more melter feed batches were produced and eleven morecanisters were filled. A fourth melter feed batch was produced during this campaign and held in the Melter Feed Tank. The DWPF then entered an extended outage during which modifications were made to the process vessel vent system. Following the outage four more canisters were filled using the remaining feed from the first campaign. The canisters produced during FA-13 were processed as shown in Table I. The melter feed for this first campaign was Blend feed (i.e. a blend of all waste types in the SRS Tank Farm). The glass and canisters from this campaign were characterized to ensure that the facility was ready for Waste Qualification Runs as well as the procedures and personnel for glass and canister characterization.

Table I

During this first melter campaign problems with pour spout pluggage occurred. The blockage was cleared but this problem continued to occur during Waste Qualification Runs and initiated an effort to design and procure a manipulator arm that could remotely clear the glass blockages.

Waste Qualification Runs

During the Waste Qualification Runs, fifty-five canisters were filled, over four melter campaigns, with simulated waste glass which was produced in accordance with the Glass Product Control Program. During these four melter campaigns, the feed coming into the DWPF went through abrupt changes in composition. The purpose of making such abrupt changes was to demonstrate that the Glass Product Control Program is able to control the glass product even when the feed composition is rapidly changing. This should enhance the confidence in the use of the program during normal operations, when changes in feed composition will be more modest.

The specific compositions processed during the Waste Qualification Runs were selected based on the thesis that if the composition/PCT correlation has been used properly to judge the acceptability of the feed, the only possible cause of failure of the Glass Product Control Program is segregation of the feed. This will occur only if the rheological properties of the material are not consistent with good mixing in the process vessels. Thus, the primary purpose of varying the feed composition during Waste Qualification Runs was to test a rangeof rheological properties, particularly for the melter, and not to qualify a set of compositions. The compositions made step changes from a Blend (design basis) composition with a dopant to track melter mixing behavior,

to a low viscosity feed, to a high viscosity feed, and back to a Blend composition. The range of the major components in the sludge and then the range of the major components in the melter feed (SME composition) over Waste Qualification Runs is shown in Table II. Although, DWPF is not qualifying a set of compositions, these compositions represent the extremes of the waste currently present in the SRS Tank Farms.

The first campaign of Waste Qualification Runs, WP-14, was the Blend feed doped with neodymium to serve as a tracer to monitor melter mixing. Neodymium was added to the SME. One batch of melter feed was produced which yielded seven canisters of simulated waste glass. Glass pour stream samples were taken from the first six of the seven canistered waste forms produced. These seven canistered waste forms were processed as shown in Table I.

An example of the importance of the SME hold point occurred during the production of this first batch of material. During the evaluation of this batch for acceptability, the liquidus criterion (glass property related to processing) was not met. However, the glass durability (i.e. predicted PCT results) was acceptable. It was determined that not enough frit had been added to the batch. The PCCS was utilized to confirm that the addition of 3600 pounds of frit to the SME would bring the batch into the acceptable region for the liquidus criterion and keep the durability acceptable. Thus, following the Glass Product Control Program, 3600 lbs of frit were added to the SME batch, the batch was agitated, and then sampled again. The results of the sample analyses were evaluated and the batch was determined to be acceptable. The SME batch was then transferred to the MFT.

Table II

During the second campaign of the Waste Qualification Runs, WP-15, four batches of high iron feed were prepared, which yielded twenty canistered waste forms. Glass pour stream samples were taken from all but the first and the eighth canistered waste forms produced. These twenty canistered waste forms were processed as shown in Table I. Prior to the performance of this campaign, problems had been experienced in pilot plant tests with melter feeds which were high in iron, and contained alkali metal ions in relatively high concentrations. The glass produced from these feeds was much less durable (as measured by the PCT) than predicted by the PCCS. Many of the glasses produced in the pilot plant testing were also phase separated, indicating that this might be the cause of the discrepancy. As a result, a variability study was undertaken with this feed. This study showed that the PCT results for the PCCS target glass were reasonably consistent with the PCCS predictions, but that there were large discrepancies between the predicted and actual PCT results for most of the other glasses tested. As called for by the GPCP, a model was developed for use on this material, called the Purex model. The resulting model essentially fits a straight line between two clumps of data at either end of the free energy of hydration range, and overpredicts PCT results of glasses in the middle of the range. This provides additional conservatism in PCT predictions for glasses with intermediate free energy of hydration values. Thus, its use would prevent production of unacceptable glass.

The decision was made to proceed with the campaign, but to control the composition of the feed through the model discussed above; through the controls already in place in the Glass Product Control Program (including the use of the PCCS); and by taking samples of each SME batch, vitrifying

them, and subjecting the vitrified samples to the PCT. If any of these indicated a problem with a SME batch, the SME batch would be remediated as called for in the GPCP, again using the same three control measures. During the third campaign of the Waste Qualification Runs, WP-16, four batches of high aluminum feed were prepared, which yielded nineteen canistered waste forms. Glass pour stream samples were taken from all but the sixteenth and seventeenth canistered waste forms produced. These nineteen canistered waste forms were processed as shown in Table I. Mercury was added to the precipitate in the salt process cell and to the sludge in the SRAT during the last batch of WP-16 to successfully demonstrate the mercury removal system.

During the production of the last WP-16 batch of melter feed the predicted composition for the SRAT was used by the DWPF engineers to diagnose an operating concern. The measured composition of the SRAT product was not consistent with the predicted composition from the PCCS. The analyzed sample results were lower in aluminum, iron, and silicon. After further investigation, it was found that foaming occurred in the SRAT during processing and sludge was carried over to the condensate tank. It is believed that this foaming occurred as a result ofthe addition of mercury to the precipitate and sludge. As a result, changes were made during processing of the remaining WP-16 batches to prevent reoccurrence. These changes included lower steam rates and an increase in antifoam additions.

During the fourth campaign of the Waste Qualification Runs, WP-17, two batches of feed were prepared. This feed transitioned back to the Blend feed from a high aluminum feed. These two batches of feed yielded nine canistered waste forms. Glass pour stream samples were taken from all but the first canistered waste form produced. These nine canistered waste forms were processed as shown in Table I. No problems had been observed with this type of feed, which was similar to the feed used in WP-14, so no special control measures were used. Mercury was added to the precipitate in the salt process cell. Noble metals and mercury were added to the sludge in the SRAT to further demonstrate the mercury removal system and simulate operations with noble metals in the sludge. The noble metals added were: ruthenium, rhodium, palladium and silver. No significant processing problems were encountered during this campaign. The mercury was successfully removed from the melter feed and no unusual problems were encountered with the addition of noble metals.

Glass and Canister Characterization

After processing was completed the filled canisters were transported to a test facility for destructive examination. The canistered waste forms were either sectioned or a portion of the canister wall removed and glass samples taken (except for two of the canisters produced during WP-17 which were archived intact). Sectioning consisted of using a band saw to slice through the entire canister at three levels. One of the slices was made at the height corresponding to the level of glass in the canister when the pour stream sample was taken. Glass samples were taken at four radial locations for each of the three levels. All the glass samples, including the DWPF pour stream samples, were characterized for chemical composition, devitrification, and durability (measured by the PCT). The chemical composition results from the glass samples were compared to the results of the melter feed sample analyses. The PCT results of the glass samples were compared to the PCT results predicted by the PCT/chemical composition correlation in PCCS. Also, the glass pour stream sample

results were compared to those of the glass samples taken directly from the canisters. These comparisons demonstrated that an acceptable product had been produced under the controls of the Glass Product Control Program.

The PCT results for all the glass produced during the Waste Qualification Runs were far below the values for the benchmark EA glass (see Table III). The mean PCT values for each of the 55 canisters produced clearly lie far below the values for the EA glass. For each of the campaigns, there is greater than 99% confidence that at least 99.9% of the least durable glass produced has better PCT results than the EA glass. This demonstrates that use of the Glass Product Control Program by theDWPF will ensure production of a product which satisfies the product consistency specification.

For all of the campaigns, there were statistically significant variations in the PCT results as a function of sample location in the canister, and sometimes from canister-to-canister. This is not too surprising, because the feed was varying for each of the last three campaigns. However, none of these affected the ability of the product to satisfy the product consistency specification. Figure 2 compares the mean PCT results for each canister to the predictions for each batch of melter feed.

Table III

The figure shows that the actual PCT results were adequately predicted and shows the lag in the glass as compared to the melter feed. This lag is due to heels in the process tanks and the melter volume.

Characterization of the canisters produced during the Waste Qualification Runs was also performed. The following activities were performed:

six canistered waste forms were tested for foreign materials by sampling the free air space above the glass level to demonstrate that DWPF can exclude foreign materials from the canister

nine canister welds were leak tested, burst tested, and microstructurally examined to demonstrate DWPF's ability to make an acceptable weld

five canistered waste forms were dimensionally measured before and after filling to demonstrate that canister filling does not significantly affect canister dimensions

Melter Mixing

The neodymium which was added as a tracer in WP-14 was tracked in the glass product and evaluated against models for a continuously stirred tank reactor and a plug flow reactor. As expected, excellent agreement was obtained between the predicted Nd concentration in the glass using the continuously stirred tank reactor model and the actual Nd concentration in the glass product. A four day hold was placed on glass pouring to allow the melter to mix after a portion of the third canister was filled. For a continuously stirred tank reactor the average concentration in the melter is the same as the outlet concentration. For a plug flow model the average concentration would be greater than the outlet. After the four day hold there was no significant effect on the difference between the predicted and actual concentrations further indicating that the DWPF melter was best represented by a continuously stirred tank reactor.

Fig. 2

TRANSITION TO RADIOACTIVE OPERATIONS

Due to SRS Tank Farm processing and blending strategies the DWPF will begin Radioactive Operations with a sludge only (no PHA)process. A frit

composition higher in alkali, to compensate for the missing PHA, will be mixed with this first radioactive sludge batch. A dilute formic acid solution will be added to the SRAT in place of the PHA. The major components of this first batch of radioactive sludge (on a dried solids wt% basis) are: Al - 6.39; Fe - 24.6; Na - 8.74; U - 3.42; Mn - 2.53; Ca - 2.38; Mg - 1.16.

This first batch of sludge has been washed five times to remove the soluble salts. Inhibited water has been added to the tank and mixing accomplished using four long-shaft slurry pumps. The wash water (containing the soluble salts) was transferred out of the tank and fresh water brought in five different times.

Currently, the DWPF is processing two sludge-only batches of simulated feed using a sludge simulant that closely matches the first batch of radioactive sludge. After the completion of these batches and startup authorization has been given, the DWPF will introduce radioactive sludge into the plant to begin the process of immobilization of high level waste in borosilicate glass.

CONCLUSIONS

The DWPF Startup Test Program has allowed the DWPF to demonstrate the functionality of its systems, exercise and refine operating procedures, and provide operators and engineers an opportunity to run the facility prior to introducing radioactive feed. During the Waste Qualification Runs portion of the Startup Test Program, DWPF has demonstrated its ability to comply with the WAPS providing assurance that the facility can produce a product acceptable for disposal. The results of this testing provide valuable experience for future operations and provide assurance that DWPF can effectively immobilize the SRS liquid high level waste in borosilicate glass.

BENCH-SCALE VITRIFICATION STUDIES WITH SAVANNAH RIVER SITE MERCURY CONTAMINATED SOIL

ABSTRACT

The Savannah River Technology Center (SRTC) has been chartered by the Department of Energy (DOE) - Office of Technology Development (OTD) to investigate vitrification technology for the treatment of Low Level Mixed Wastes (LLMW). In fiscal year 1995, LLMW streams containing mercury were targeted. In order to successfully apply vitrification technology to LLMW containing mercury, the types and quantities of glass forming additives necessary for producing homogeneous glasses from the wastes had to be determined and the treatment for the mercury portion had to also be determined. Selected additives had to ensure that a durable and leach resistant waste form was produced, while the mercury treatment had to ensure that hazardous amounts of mercury were not released into the environment.

The mercury containing waste selected for vitrification studies at the SRTC was mercury contaminated soil from the TNX pilot-plant facility at the Savannah River Site (SRS). Samples of this soil were obtained so bench-scale vitrification studies could be performed at the SRTC to determine the optimum waste loading obtainable in the glass product without sacrificing durability and leach resistance. Vitrifying this waste stream also required offgas treatment for the capture of the vaporized mercury. Results indicated that a durable, leach resistant glass waste form capable of passing the Product Consistency Test (PCT) and the Toxicity Characteristic Leaching Procedure (TCLP) could be produced. The optimum glass feed composition contained 60 weight percent soil and produced a soda-lime-silica glass when melted at 1350C. The glass additives used to produce this glass were 24 weight percent Na_2CO_3 and 16 weight percent $CaCO_3$.

The proposed mercury capture method was a Na_2S wash bottle followed by a NaOH wash bottle. The volatilized mercury entered the first wash bottle through a bubbler with the intent of converting it to Hg_2S, a very stable form of mercury. If successful, no further treatment of the mercury would have been needed. However, attempts to capture the volatilized mercury in a Na_2S solution wash bottle were not as successful as anticipated. Maximum mercury captured was only about 2% of the mercury contained in the feed. Efforts then shifted to condensing and capturing the volatilized mercury. Condensing attempts were much more successful at capturing the vaporized mercury. This captured mercury could then be treated on a mercury specific resin after digestion of the volatilized mercury.

INTRODUCTION

The DOE has chartered the Mixed Waste Focus Area (MWFA) to investigate waste forms for LLMW. Vitrification or high-temperature thermal treatment of the wastes is a main focus of the MWFA investigations. The MWFA has funded the SRTC to perform vitrification and high-temperature thermal treatment studies on LLMW. The SRTC's efforts have focused on treatment of LLMW sludges, soils, debris, resins, and other solid wastes.

A large focus of the efforts has been treatment of soils due to the large volume of contaminated soil that exists at the SRS and other DOE sites. Soil at the SRS has been contaminated with both radioactive and hazardous constituents as a result of accidental spills and storage of liquid wastes. Some of these soils have been exhumed and containerized, but most have not and will not be until a treatment method is determined.

A small amount of contaminated soil was exhumed at the TNX pilot-plant facility during routine maintenance operations. This soil was characterized and found to contain elevated levels of mercury. Two samples of this soil, one with mercury levels below TCLP limits and one with elevated levels of mercury, were obtained by SRTC for bench-scale vitrification studies. Previous studies by SRTC had shown that vitrification of soil was a viable option (1) and that vitrification offgas systems could successfully capture mercury.

For the mercury soil vitrification viability studies at the SRTC, bench-scale studies were performed with the two soil samples to determine the necessary glass additives for producing homogeneous glasses. The homogeneous glasses produced were subjected to leach testing to determine glass durability, since it was important to ensure that the hazardous/radioactive constituents were incorporated in the glass matrix. Since the waste contained mercury which is not incorporated in the glass matrix, an offgas system had to be installed on the furnace. The intent of this system was to collect the vaporized mercury, as well as convert the mercury to a stable form.

The composition of a sample of the TNX soil with less than TCLP levels of mercury was chemically characterized to determine the chemical constituents. It was suspected that the SRS soil contained mostly SiO_2 and this was confirmed by the chemical analyses. The chemical composition of the soil is given in Table I on an oxide basis. The previously determined total mercury in the less than TCLP limit sample was 1.92 ppm, while the high mercury sample contained 264 ppm total mercury.

Table I

Previous bench-scale studies with simulated SRS soil had determined that durable and homogeneous glasses could be made by using the soda-lime-silica ternary system. Waste loadings in these glasses were 55 and 58 wt%. The glass forming additives used were Na_2CO_3 and $CaCO_3$, and all glasses were melted at 1150C (1). Since these glasses were made using simulated soil, bench-scale tests with actual soil had to be performed to determine the validity of the glass compositions.

LOW MERCURY SOIL EXPERIMENTS

In order to determine the applicability of the previously developed glass compositions for actual SRS soil, two of the glass compositions were selected for bench-scale testing. A higher waste loading batch composition was also derived to ensure that the optimum waste loading had been found. The compositions tested on an additive basis are shown in Table II. Two additional batch compositions were also tested based on the results of these first bench-scale trials and these batch compositions are also shown in Table II.

Table II

The batches listed in Table II were mixed using the low mercury soil sample and reagent grade chemicals. The batches were then placed in high purity alumina crucibles and covered. Batches 1 - 3 were melted at 1150C for 4 hours and visually examined after air quenching. A description of the resulting products are given in Table III. Since it appeared that batch 3 resembled homogeneous glass the most, a higher waste loading was tested as batch 4. This batch was melted at 1175C and its appearance is also described in Table III. As noted in Table III, some of the glasses appeared to have some unreacted material around the crucible edges, it was believed that this material was unreacted SiO_2. This was confirmed by Scanning Electron Microscopy (SEM). Since the material was confirmed to be SiO_2, batch 3 was remelted at 1350C to determine if higher temperatures would fully react the feed material. This resulted in a very homogeneous looking glass with only minimal unreacted particles of SiO_2. Attempts were also made to diminish the formation of this SiO_2 layer by reducing the CaO:Na_2O ratio, since the presence of Na_2O tends to make SiO_2 more soluble. This composition was batch 5 and was also melted at 1350C. The appearance of the final product is also given in Table III. Since batch 3 produced the most homogeneous glass, it was characterized for chemical composition and phase assemblage. Durability tests were also performed using the PCT. The composition of the batch 3 glass is given in Table IV. The only substantial oxide components found in the glass were the SiO_2 and Al_2O_3 from the soil and Na_2O and CaO from the glass additives. X-ray diffraction (XRD) of the glass indicated that the resulting glass was amorphous. SEM analyses verified the amorphous state of the glass, as well as confirmed the presence of small amounts of unreacted SiO_2 at the glass surface.

Table IV

In order to determine the durability of the batch 3 glass, the PCT was performed. The PCT is the standard test used for determining the durability of High Level Waste (HLW) glasses and is performed in an alkaline driven environment. It is a 7-day test performed at 90C in ASTM type I water. The test is performed on 100-200 mesh glass particles and the resulting leachate is analyzed for elemental concentrations (2). These concentrations are then normalized for the elemental glass constituents.

At present no PCT acceptance criteria exist for LLMW glasses. However, the acceptance criteria have been established for HLW glasses. The measured normalized releases for the Environmental Assessment (EA) glass, which is the benchmark for the Defense Waste Processing Facility (DWPF) HLW glass, are 3.922 g/L Si, 13.346 g/L Na, and 16.695 g/L B. The measured leachate pH is 11.91 (3). The normalized PCT results for the batch 3 glass were 0.35 g/L Si, 5.90 g/L Na, and 0.00 g/L B. The measured pH was 11.85. Normalized PCT results for the batch 3 glass were significantly less than the limits for Si and B, and the result for Na was 2.5 times less. These results indicate that the resulting glass product was a durable wasteform.

The TCLP was not performed on the glass since no hazardous constituents other than mercury were present in the soil. Since it was known that the mercury would volatilize during vitrification, no mercury should have remained in the glass to leach during the TCLP.

ELEVATED MERCURY SOIL EXPERIMENTS

Before the treatability studies with the elevated mercury soil sample could be performed in the bench-scale furnace, the offgas collection system had to be fabricated and installed. A detailed drawing of the offgas system fabricated is contained in Fig. 1. The intent of the system was to contain all of the volatile mercury in the quartz lines of the system. Using forced air on the seal of the crucible and vacuum pressure on the end of the system line, mercury was forced through the quartz tubing to the first wash bottle containing Na2S. The vapors entered through the dip tube and were bubbled in the Na2S. Vapors from this tube were drawn through the NaOH wash bottle by the vacuum at the end of the line. In this second bottle, the sulfuric acid gases generated from the first wash bottle were neutralized by bubbling through the NaOH solution. All vapors generated from this bottle were vacuumed through a hood exhaust that was in line with the building offgas system.

Fig. 1

The offgas system was seated in a Thermolyne furnace. For bench-scale vitrification of the elevated mercury soil, batches were heated in a 50 mL platinum crucible to a minimum of 690C and then the final product was transferred to an alumina crucible and melted in a Lindberg high temperature furnace at 1350C. Due to chemical hood space constraints and the desire not to drill a 2 inch hole in the Lindberg furnace, batches were heated using the Thermolyne furnace and the offgas system until temperatures substantially above the mercury vapor point were achieved. Three batches of approximately 50 grams of the same batch composition tested with the low mercury soil (batch 3) were mixed. These batches contained 60 wt% of the elevated mercury soil, 16 wt% CaCO3, and 24 wt% Na2CO3. Three separate trials were performed with these feeds, with two of the batches of feed (Trial 2 and 3) containing 500 ppm of Cs and Ce as radioactive surrogates. In each trial, the batch was placed in a platinum crucible, which was placed inside the quartz containment vessel. The inner containment section was placed directly on the crucible, where it actually overlapped the crucible top by about a 1/4 inch. The vacuum and air were started and then the furnace was turned on. The furnace was heated at a rate of approximately 10C/min until it reached the temperatures shown in Table V. Once at temperature, the temperature was maintained for 2 hours. After the 2 hours, the furnace was turned off and the system was allowed to cool. During the heat-up, maintain temperature, and cool-down cycles, the temperature of the furnace and the thermocouple in the offgas line were recorded. Maximum recorded offgas line temperatures were 269C. Once the furnace had cooled, the air and vacuum supplies were turned off.

Table V

The amounts and concentrations of the wash bottle solutions are also contained in Table V. Trial 3 contained a stronger concentration of Na2S in an attempt to capture more of the mercury. Samples of the two wash bottles were taken so the chemical constituents could be analyzed.

The platinum crucibles of feed from each trial were removed from the mercury collection system in the Thermolyne furnace and placed in a programmable Lindberg furnace and heated to 1350C. After 4 hours at temperature, the crucibles were removed from the oven and the glasses were air quenched to room temperature.

Glass Analyses

Once the glasses had cooled, they were broken out of the crucible for chemical composition, phase assemblage, and durability determinations.

All glasses were blue-green in appearance with small amounts of unreacted SiO_2 at the surface. Durability was determined in alkaline and acidic conditions using the PCT (2) and TCLP (4), respectively. The PCT results were compared against the EA glass accepted values for HLW (3), while the TCLP results were compared to the more restrictive of the TCLP limits, Resource Conservation and Recovery Act (RCRA) Land Disposal Limits, or the Universal Treatment Standards (UTS).

The chemical composition of the glasses produced from each trial are contained in Table VI. Compositions were fairly consistent between each trial, with the exception of the Cs_2O and CeO_2, since these were not added to the batch for the first trial. Some soil variability was evident by the elevated Al_2O_3 and lower SiO_2 numbers compared to the low level mercury soil glass. Part of this variability can be attributed to differences in soil composition and part can be contributed to incomplete mixing of the feed material. Glass analyses results indicated that almost all of the Cs_2O was encapsulated in the glass, which was shown by a comparison of the feed and glass analyses results. For both trials, more Cs_2O was actually found in the glasses, which was probably due to incomplete mixing in the feed sample analyzed. In both cases, the amount retained was greater than the theoretical loading. CeO_2 concentrated in the glass matrix for trial #2, proven from a comparison of the feed to glass results, but results for trial #3 were inconclusive since both the feed and glass levels for Ce were less than the detection limit. HgO concentrations in the feed for each trial were 0.055, 0.077, and 0.015 wt% respectively. For the final glass products, the HgO levels were at the detection limits and were roughly the same irrelevant of the feed concentration levels. This was expected since all of the mercury in the feed was expected to volatilize from the feed. The Fe^{2+}/Fe^{3+} ratio was also measured for the glasses produced, and the results indicated that the melting conditions were oxidizing (average ratio was 0.0494).

Table VI

Phase assemblage was determined using XRD and SEM analyses. In all cases, the glasses were amorphous when analyzed by XRD. SEM analysis of the glasses confirmed the presence of small amounts of unreacted SiO_2. This SiO_2 would likely be fully reacted at elevated temperatures or in a melter environment due to the mixing that occurs.

The PCT was performed on the glasses from each trial. The normalized results are given in Table VII. Normalized releases were comparable to the releases for the low mercury soil glass, which were better than the HLW EA glass PCT limits (3). Na release was once again the highest relative to the HLW EA acceptance criteria, but it was still much better than the EA glass. Trial #2 glass had the lowest Na release, which was consistent with the lowest Na_2O and SiO_2 content and the highest CaO and Al_2O_3 content in the elevated mercury glasses. However, when compared to the low mercury glass, trial #2 glass had higher Al_2O_3, CaO, and Na_2O concentrations and a lower SiO_2 content, which resulted in a more durable glass. These results would seem to indicate that the effects of high concentrations of Na_2O on durability can be offset by increases in Al_2O_3 and CaO concentrations and decreases in the SiO_2 content. This better durability may also have been the result of the increases in Fe_2O_3 content in the trial #2 glass since Fe_2O_3 is known to have a positive effect on durability. Glasses from the second and third trial had minimal releases for Ce (<0.020 ppm detection limit) and Cs (<1 g/L), which were the radioactive surrogates.

Table VII

The TCLP was performed on the first and second glasses produced from the trials because of the elevated levels of mercury in the feed. The TCLP was mainly performed to determine the leaching behavior of mercury since it was the only hazardous element of concern. As expected, mercury leaching was less than the detection limit of 0.008 ppm. The TCLP was not performed on the third glass, since the releases for the first two were below the detection limit.

Offgas System Analyses

The aqueous products contained in the wash bottles after the three trials were analyzed for chemical content. Each solution was analyzed using Inductively Coupled Plasma Emission Spectroscopy (ICPES) to determine the major cation concentrations, Atomic Absorption (AA) to determine the Cs content, Ion Chromatography (IC) to determine the major anions present, and cold vapor techniques were used to determine the mercury content. The components of each wash bottle are presented in Table VIII.

Table VIII

Results presented in Table VIII indicate that the mercury was not sufficiently being captured and converted to Hg_2S as anticipated. Total mercury captured for the trials were 0.03%, 1.97%, and 0.09%. The second trial captured the most mercury and it was the only solution which changed colors. The solution in the Na_2S bottle exhibited a blue-green color by the end of the trial. The higher concentration of Na_2S in the wash bottle in the third trial did not seem to help capture the mercury. Even though the Na_2S wash bottle was not effective in capturing the mercury, the NaOH bottle was successful in scrubbing the acid gases generated from the first bottle which is indicated by the general decrease in the pH and the capture of sulfate. No Ce was detected in the offgas system, which helps support the theory that it is all entrained in the glass waste form. Total Cs detected in the offgas system for each trial was less than 0.5% of the total Cs in the feed.

In order to more efficiently capture the volatilized mercury, the wash bottles were replaced with a mercury condenser kept below 10C and a KOH final wash bottle. The same glass formulations and melting schedules were used from the earlier tests. The resulting product was a homogeneous and durable glass similar in composition to the glass from trial #3 and with similar PCT results. Almost all of the volatilized mercury was captured and/or condensed. No mercury carried over into the KOH wash bottle. The mercury condensed was dissolved into an aqueous media for treatment on a mercury specific resin. This resin is capable of incorporating the mercury so it does not leach from the resin when subjected to the TCLP.

CONCLUSIONS

Crucibles studies with mercury contaminated SRS soil have shown that the soil can be converted to a durable, leach resistant glass wasteform. Optimum waste loading was determined to be 60 wt%, with 24 wt% Na_2CO_3 and 16 wt% $CaCO_3$ used as the glass forming additives. Attempts to capture and convert the volatilized mercury into stable Hg_2S were not as successful. Only 2% of the total mercury was captured in the offgas system. However, it was shown that by using conventional condensers, mercury could be successfully captured and/or condensed in the offgas system. Once captured, the mercury could be converted to a stable form on leach resistant mercury specific resin.

ACKNOWLEDGEMENTS

Funding for this research and development work was provided by the Department of Energy - Office of Technology Development under the auspices of the Mixed Waste Focus Area and Technical Task Plan SR1-3-20-04 and contract No. DE-AC09-89SR18035 with the U.S. Department of Energy.

DEVELOPMENT OF AN INTEGRATED FACILITY SPECIFIC WASTE ACCEPTANCE CRITERIA AT THE SAVANNAH RIVER SITE

Paul D. Hunt
James R. Cook
Elmer L. Wilhite
Westinghouse Savannah River Company

ABSTRACT

The Department of Energy's (DOE) Savannah River Site (SRS) has developed an integrated facility specific Low Level Waste (LLW) Waste Acceptance Criteria (WAC) (1) designed to meet DOE Order 5820.2A (2) requirements and implement limits and assumptions established in a facility specific radiological performance assessment (RPA) (3) and safety analysis report (SAR) (4). As the SRS E Area Vault (EAV) facility is the first in the DOE complex to have an approved PA, the EAV WAC is the first in the complex to fully implement PA results into LLW acceptance criteria. Enforcement of PA derived limits ensures long-term compliance with DOE 5820.2A performance objectives. Integration of SAR based limits into the WAC ensures protection of workers and the public during facility operations. The composite WAC establishes the foundation for safe LLW disposal at SRS.

In developing facility specific acceptance criteria, SRS has necessarily stepped away from implementation of industry standard limits promulgated in the Nuclear Regulatory Commission's Title 10 CFR Part 61 (5). Development and implementation of facility specific LLW acceptance criteria provides for special consideration of unique waste streams produced in the site's numerous waste generating activities. Of equal importance, development of facility specific acceptance criteria has enabled SRS to employ a technically sound, graded approach for isolation and disposal of LLW. SRS's transition to fully compliant LLW disposal activities represented a significant change in operations and infrastructure. The facility and site specific approach applied in development of the acceptance criteria facilitated generator implementation and offered an optimal balance of technical requirements and cost efficient disposal options.

BACKGROUND

With issuance of Order 5820.2A in 1988, DOE established performance objectives to protect the public, intruders, and groundwater from LLW disposal activities. In response to the Order, SRS initiated the E Area Vault project to provide concrete barrier isolation between LLW and the environment. As DOE Headquarters prepared guidance for implementation of new performance assessment requirements, SRS proceeded with design and construction of three sets of disposal vaults. The Low Activity Waste Vault (LAWV) was designed for disposal of contact handled (<200 mrem/hr) waste. The Intermediate Level Tritium Vault (ILTV) was constructed for disposal and grout encapsulation of tritium contaminated wastes. The Intermediate Level Non-Tritium Vault (ILNTV) was designed for disposal and grout encapsulation of remote handled waste (>200 mrem/hr). A later addition to the EAV facility provided for shallow land disposal (non-vault) of slightly contaminated soil. Shallow land disposal of large highly activated components generated by the Department of Defense's Naval Reactor program has also been proposed.

The intent of both DOE 5820.2A and 10CFR61 is completion of a site specific PA in parallel with facility design so as to allow the PA to influence design requirements. Due to the near term need for additional disposal capacity and the infancy of performance assessment requirements, vault designs proceeded without the benefit of PA results. As such, the PA and SAR evaluated actual facility designs and operating practices. So as not to restrict waste disposal, the EAV PA was drafted to assess the maximum allowable inventory within constraints of DOE 5820.2A performance objectives. The PA initially considered 730 radionuclides that could potentially exist in SRS waste streams. Simple screening analyses based on half-lives and dose contributions reduced the number of radionuclides requiring detailed pathway analyses to 58. Detailed analyses further reduced this number, establishing maximum single isotope facility inventory limits for 37 radionuclides. As expected, the majority of the resulting limits were for long-lived radionuclides. Two notable exceptions were H-3 limits derived through the atmospheric pathway analysis and Cs-137 limits from the intruder scenario.

Enforcement of these 37 single isotope, performance based limits required utilization of sum-of-fractions inventory controls. Given the nature of changing missions at SRS, this approach for establishing and managing performance limits provided increased flexibility versus analyzing a fixed facility inventory.

The SAR necessarily evaluated potential exposures from a range of credible natural phenomena, criticality, and accident scenarios. An entry point for SAR preparation is establishment of a facility hazard classification in accordance with the Hazard Assessment Document (HAD) requirements defined in DOE Standard 1027 (6). Projections of facility inventories established a facility hazard classification and set an upper limit on total facility inventory.

As accident analyses typically involve individual or multiple containers, the SAR also required development of estimated container inventories. Due to the number of historical and ongoing nuclear processes at SRS, the composite of facility and container inventories included 48 radionuclides. The SAR produced container and facility inventory limits for each of these 48 radionuclides. The SAR also established container and facility inventory limits for fissile and fissionable isotopes and enforced regulatory driven transuranic limits.

DEVELOPMENT OF INTEGRATED WASTE ACCEPTANCE CRITERIA

The EAV WAC provided the vehicle with which to compile the 37 performance and 48 safety based limits and communicate resulting limits to waste generators. In developing the WAC, key objectives included:

- enforcement of PA and SAR limits, including controls on fissile and transuranic isotopes
- encompass majority of SRS waste streams, minimizing need for special deviations to acceptance criteria
- communicate key requirements needed to uphold assumptions made in the PA and SAR
- facilitate generator efforts to comply with DOE 5820.2A characterization and certification requirements

The composite of 37 performance and 48 safety based limits produced a total of 68 radionuclides requiring consideration for acceptance criteria radionuclide limits. In order to provide a common basis for evaluation, PA and HAD facility inventory limits were divided by the expected number of packages, producing limits based on the "average" package. Package based WAC limits were chosen over concentration limits, making implementation more compatible with generator strategies to characterize individual packages (i.e. dose-to-curie). Clearly, implementation of "average" package limits would have resulted in excessive requests for deviations to accommodate the many unique SRS waste streams. As such, three initiatives were undertaken to better refine the WAC and ease generator characterization requirements.

An extensive study of SRS radionuclide distributions was undertaken to better identify radionuclides of concern to vault operations. The study grouped the over 200 SRS radionuclide distributions into five representative waste streams (fission products, induced activity, tritium, uranium, and plutonium). A review of over 1,000 actual waste package inventories provided typical container loadings for each of the five representative waste streams. These typical container loadings were used to construct container and facility inventories which should reasonably bound future receipts. This study provided a basis for manipulating the "average" container limits to better accommodate SRS wastes.

A separate study was conducted to evaluate the range of special nuclear materials produced at SRS, many of which were retained in the PA and SAR analyses due to their long half-lives and dose contributions. A search of records maintained within the accountable material controls program identified upper bounding site-wide inventories for a number of special nuclear materials. These bounding inventories established that some special nuclear materials, such as curium and californium, were not produced in quantities that could impact long term vault performance. The study provided a basis for eliminating these radionuclides from the WAC.

A third study evaluated the fixed relationships of many radionuclides within SRS waste streams. In such cases, including the obvious parent-daughter relationships, limit controls for one radionuclide restricted the inventory of one or more associated radionuclides. As an example, the PA limit for Cs-137 and its fission product relationship with Cs-134 and Cs-135 necessarily limited the inventory of Cs-134/135 well below levels of concern in either the PA or SAR. This study provided the basis to further reduce the number of radionuclide limits retained in the WAC.

When paired with PA and SAR limits, the results of these three studies enabled the authors to reduce the number of radionuclides retained in the

WAC to 22 radionuclides. Comparison with the projected facility inventories permitted adjusting package limits to best accommodate the wide range of expected SRS radionuclide distributions while still upholding the basis for the facility limits. Figure 1 below identifies the basis documents for the 22 radionuclide limits in the final WAC.

Fig. 1

This strategy for development of acceptance criteria has been applied to specific waste streams, further "personalizing" the SRS LLW acceptance criteria. Examples of this unique application include earthen trenches for slightly contaminated soil and proposed mounded disposal of DOD's Naval Reactor components. In both examples, waste stream specific analyses present technically defensible disposal options to the more costly vault disposal. Implementation of these waste form specific disposal options dictates that the WAC impose more stringent waste form requirements to uphold assumptions in the PA and SAR analyses.

RESULTS AND CONCLUSIONS

Implementation of waste acceptance criteria for the E Area Vaults has brought SRS into compliance with DOE 5820.2A disposal requirements. The final set of radionuclide limits necessarily differs from those established in 10CFR61. As expected, intruder based limits were reasonably similar as environmental and geographical differences have limited impact on these scenarios. EAV limits derived from the groundwater analyses did vary significantly from limits established in 10CFR61. Again, this was expected given the humid SRS environment and the limited groundwater analyses supporting 10CFR61 limits. Table I below provides a comparison of some of these limits (EAV limits converted to concentration basis for comparison purposes).

Table I

Initial drafts of the acceptance criteria contained all of the composite 68 radionuclides identified in the PA and SAR. The concept of 68 radionuclide limits for each of the multiple disposal options in addition to the more stringent LLW controls promulgated through 5820.2A, brought generator implementation of the Order to a near stand still. The studies outlined above produced a streamlined set of 22 facility and site specific radionuclide limits. This approach substantially eased generator implementation while still enforcing Order requirements and critical PA and SAR assumptions.

Implementation of the PA and SAR limits has been further facilitated through a site-wide Waste Information Tracking System (WITS). WITS enables generators to select approved containers, create shipments, check container inventories against radionuclide limits, and print waste shipping manifests. Within the disposal facility, WITS provides capabilities for ensuring compliance with the entire range of container and facility inventory limits, including PA, SAR, criticality, transuranic, and greater-than-class C.

The facility and site specific approach requires added attention when accepting offsite waste shipments as some assumptions and evaluations would not apply to offsite generators. This increased scrutiny is accomplished through the generator certification process and evaluation of individual waste stream characterizations. The concept of developing acceptance criteria for specific waste forms has been applied to offsite generators as exemplified in the ongoing development of unique limits for Naval Reactor components.

The EAV WAC has been successfully implemented at SRS. The strategy taken has enabled SRS to enforce a multitude of requirements through a single set of radionuclide limits. The final WAC limits are unique to EAV and bound the majority of SRS waste streams. The approach can be applied to specific waste streams, providing for continued flexibility for future waste receipts. The concept of facility and site specific acceptance criteria does require increased monitoring to ensure key assumptions are upheld.

OPPORTUNITIES FOR FURTHER STUDIES

Many opportunities exist for continued enhancements of the acceptance criteria. Recently completed performance analyses of ashcrete and blowcrete to be generated in SRS's Consolidated Incineration Facility indicate this stabilized waste form can be disposed in earthen trenches. If approved and implemented, this waste stream specific acceptance criteria will optimize utilization of existing disposal capacity while enforcing DOE 5820.2A performance objectives. Other opportunities for waste stream specific analyses include vitrified waste forms and increased utilization of earthen trenches for organic and non-organic rubble and debris.

LOOKING AHEAD: HOW TO MEET INCREASING WASTE CERTIFICATION REQUIREMENTS WITH LESS BUCKS

Michael B. Hughes
Gerald W. Faulk
Westinghouse Savannah River Company
Solid Waste Management Department
Aiken, SC 29802

ABSTRACT

Construction of the Savannah River Site (SRS) was started by the U.S. Government in 1950. The site covers approximately 300 square miles located along the Savannah River near Aiken, South Carolina. It is operated by the U.S. Department of Energy (DOE). Operations are conducted by managing and operating contractors, including the Westinghouse Savannah River Company (WSRC). Historically, the primary purpose of the SRS was to produce special nuclear materials, primarily plutonium and

tritium. In general, low-level radioactive and mixed waste is generated through activities in operations.

Characterization and certification of the low-level radioactive and mixed waste generated by forty seven independent operating facilities at The Savannah River Site (SRS) was completed in 1995. A generic waste characterization protocol and methodology enabled the efficient characterization of over 140 waste streams. This strong program base has allowed the site to meet increasing waste certification requirements cost effectively.

After approving the waste certification programs for 47 generators of low-level radioactive and mixed waste, Westinghouse Savannah River Company (WSRC) moved forward to implement a performance-based approach for assuring that approved waste generators maintained their existing waste certification programs during a time that they were also expanding those same programs to qualify for additional disposal and treatment facilities at SRS. WSRC implemented the Waste Certification Review Program, which is comprised of two sitewide programs, waste generator self-assessments and Facility Evaluation Board reviews, integrated with the WSRC Solid Waste Management Department Waste Verification Program Evaluations. The waste generator self-assessments ensure compliance with waste certification requirements, and Facility Evaluation Board reviews provide independent oversight of generators' waste certification programs. Waste verification evaluations by the TSD facilities serve as the foundation of the program by confirming that waste contents and generator performance continue to meet waste acceptance criteria prior to shipment to treatment, storage, and disposal facilities.

TRANSITION TO A WASTE CERTIFICATION REVIEW PROGRAM

The WSRC Solid Waste Management Department (SWMD) has implemented an integrated and cost effective Waste Certification Review Program for approved generators of low-level radioactive waste and low-level mixed waste. The program assures SWMD that approved waste generators maintain their approved waste certification programs.

New waste generator certification programs are approved through the established Waste Certification Approval Program. Once approved, waste generators undergo periodic review by the TSD under the protocol of the Waste Certification Review Program described below.

Both programs require review of waste generator certification programs for compliance with waste acceptance criteria of treatment, storage, and disposal (TSD) facilities. The Waste Certification Review Program integrates the use of existing SRS programs and waste verification to provide the assurance that approved generators maintain their required waste certification programs. It also integrates the Facility Evaluation Board (FEB) reviews, waste generator self-assessments and SWMD waste verifications. Waste verification evaluations coupled with FEB reviews and self-assessments provide a cost effective approach to waste certification for approved waste generators.

The foundation of the Waste Certification Review Program, the Waste Certification Waste Verification Program Evaluations, permits the SWMD to address the DOE Order 5820.2A requirement that waste generator certification programs undergo periodic audit by the operators of the facilities to which waste is sent. Waste verification evaluations are the method used to confirm that waste contents and waste generator performance meet the DOE Order requirements for waste certification.

Waste verification evaluations involve the inspection and verification of waste generator shipments by various methods to ensure consistency between the shipping documentation and the received wastes. As performed at most DOE and commercial facilities, waste verification confirms that the waste from a particular generator meets both general and specific verification criteria.

WASTE VERIFICATION PRACTICES

SWMD waste verification procedures check and document that waste generators' compliance with TSD waste acceptance criteria. These procedures require collecting and reporting inspection results for feedback on waste generator performance for use in the Waste Verification Program Evaluations. Procedures for visual inspection of low-level waste call for the selection of waste containers based upon generator shipments. SWMD establishes the frequency for verification of containers from waste generators. Verification frequency is adjusted according to the generators' performance. It is noteworthy that an initiative was implemented sitewide to improve the effectiveness of visual inspections of waste bags. Clear polyethylene plastic bags are being procured for improved visibility of waste bag contents. The new bags are being used by waste generators for improved inspection capability.

SWMD receipt inspection results are collected from all waste generators in the Waste Verification Program. Non-destructive examination (NDE), non-destructive assay (NDA), and chemical screening techniques similar to those employed at other DOE and commercial facilities will be phased into the program. Inspection and verification are results included in the Waste Verification Program. Nonconformances found during verification are identified, tracked, and corrected with waste generators prior to formal acceptance of the waste.

NDE, NDA and chemical screening are important features of any waste verification program. These methods provide a non-intrusive means of screening and quantifying radiological and chemical constituents in a waste container. SWMD compared NDE, NDA and chemical screening methods at other DOE and commercial TSD facilities and found the emphasis and level of scrutiny vary between facilities, based on federal and state regulatory requirements. Some features of radioisotopic assaying, radiography, and chemical screening are:

Radioisotopic Assaying - a method of identifying and quantifying radioisotopes in a given waste container. The purpose of the assay is to verify radioisotopic content to the extent and accuracy reported on the waste characterization forms for the waste stream being checked. Assaying may also be used to verify that low-level waste is below the transuranic threshold limit (100 nCi/g).

Radiography - a means of inspecting a container for prohibited items listed in the waste acceptance criteria. There are two technologies available, real-time radiography and digital radiography. Real-time radiography allows for a virtual "real-time" image of waste container contents and typically includes videotaping capabilities. digital radiography takes an image of the container contents and digitizes the picture such that it can be viewed and stored electronically.

Chemical Screening - analytical tests performed on representative samples of the waste. Typically, these analyses are performed to determine the presence of polychlorinated biphenyls, Resource Conservation Recovery Act or Toxic Substance Control Act controlled substances which, if found, would categorize the waste as mixed rather

than low-level waste. The specific analysis performed is dependent on the waste acceptance criteria. A field-deployable lab cart is used to perform gross screenings and, if necessary, samples are then sent to an analytical laboratory for more in-depth analysis.

These NDE, NDA and chemical screening methods are available both onsite and offsite; however, the associated costs and logistics vary greatly. After evaluating the various options and considering the requirements of DOE Order 5820.2A, SWMD selected a combination of assay, radiography and limited chemical screening to verify that incoming waste is in compliance with the waste acceptance criteria. Radioisotopic assay and digital radiography were the most cost effective and logistically feasible approaches. A portable kit is being obtained for chemical screening, and personnel are to be trained accordingly for use on a limited basis and under special circumstances to analyze various homogeneous waste forms.

PERFORMANCE BASED EVALUATIONS

Information on waste generators is collected and analyzed from receipt inspections, random visual inspections, shipment and characterization verifications, and NDE and NDA results when available. Other performance information, such as nonconformance reports, is considered as appropriate. Overall, this information provides a performance-based method of reviewing generator waste certification programs and a method for adjustment of waste verification.

In general, SWMD evaluates approved waste generators on a periodic basis. Waste Certification Assessment and Minimization procedures are developed to describe the evaluation process, evaluation criteria, reporting, and department required actions, as appropriate. In the evaluation process, waste verification results are discussed with waste generators, documented for trending purposes, and serve as a tool for continuous improvement. Performance areas requiring improvement or correction are identified on a case-by-case basis and presented to waste generators for resolution.

SWMD uses performance evaluation criteria to review the approved status of generator waste certification programs. The performance criteria are improved with its application to assure consistent evaluations and provide a mechanism to identify waste generator strengths and areas needing improvement. The performance criteria are structured to provide a graded method for evaluation of performance. Each waste generator's performance is graded as satisfactory, needing improvement, weak, or a strength area based upon an evaluation of the information collected over a specified evaluation period. The evaluation criteria define the basis for the grading of waste generator's performance from waste verification results.

CONCLUSION

After waste generator certification programs were initially approved and operating, SWMD needed a real-time waste verification program to confirm waste contents and evaluate generator performance. Waste verification is the foundation of Waste Certification Review Program, which includes waste generator self-assessments and independent oversight by the FEB. Random visual inspections of waste shipments, digital radiography, and radioisotopic assay are performed and results are evaluated with receipt inspection information to confirm generators are maintaining their waste certification programs. SWMD performs a review of approved waste generator status using information from the Waste Verification Program as part of the Waste Certification Review Program.

Therefore, as the SRS Waste Certification program matured with the initial waste certification assessments for 47 facilities at the SRS, innovative methods were developed that provided the following cost effective steps for the re-assessment and new assessments: 1) The Consolidated Incinerator Facility and the required periodic assessments were combined, 2) Waste generators were grouped by division programs to expedite completion of re-assessments and 3), Tiered oversight from three existing site assessment programs was established to gain economy of effort. In combination this will result in an annual cost saving of approximately $600,000 for the site.

DRIVING DOWN THE COST OF CLEANUP: ER INITIATIVES AND INNOVATION IN PLACE AT THE SAVANNAH RIVER SITE

W. Dean Hoffman
Westinghouse Savannah River Co.

ABSTRACT

This paper will describe how four (4) major initiatives developed at the Savannah River Site (SRS) have combined to save millions in their Environmental Restoration Program. The four initiatives are 1) streamlined sampling approaches; 2) approved standard designs and remedies; 3) minimization of investigative derived wastes; and 4) reduced groundwater monitoring requirements.

Specifically streamlined sampling approaches will show how early scoping of waste site characterization has resulted in more efficient sampling to reach a site profile. In addition, this initiative has generated the grouping of sites into characterization envelopes which can be used to further reduce sampling and facilitate the selection of a remedy. SRS will share its experience in this area.

The concept of the Approved Standard Corrective Action Design (ASCADtm) has been developed at SRS and makes full use of streamlining. This concept is an innovative way of defining characterization conditions and matching them with standard environmental restoration remedies. SRS has this concept endorsed by its regulators and is using it.

Minimizing the cost of investigative derived wastes is an area where SRS can show success in managing a complex-wide issue. Purge water from groundwater wells in radioactive and mixed waste burial grounds can be treated in a permitted on site facility. SRS will share this experience and has regulatory approval to move ahead with this initiative.

Quarterly groundwater well monitoring requirements were costing the SRS ER Program over $10 million annually. By focusing data needs and communicating with regulators, permit requirements have been changed to allow a more cost efficient program without significantly sacrificing environmental information. Other DOE Programs should benefit from this experience.

INTRODUCTION

This paper describes how four (4) major initiatives developed at the Savannah River Site (SRS) have combined to save millions in the Environmental Restoration Program. The four initiatives are 1) reduced groundwater monitoring requirements; 2) minimization of investigation derived wastes; 3) streamlined sampling approaches; and 4) approved standard designs and remedies.

Quarterly groundwater well monitoring requirements were costing the SRS ER Program $12 million annually. By focusing data needs and communicating

with regulators, permit requirements have been changed to allow a more cost efficient program without impacting key environmental information. The cost today of this program is now less than $8 million annually.
Minimizing the cost of investigation derived wastes is an area where SRS can show success in managing a complex-wide issue. Purge water from groundwater wells in radioactive and mixed waste burial grounds can be treated in a permitted on site facility. SRS will share this experience and has regulatory approval to move ahead with this initiative.
Streamlined sampling approaches will show how early scoping of waste site characterization has resulted in more efficient sampling to reach a site profile. In addition, this initiative has generated the grouping of sites into characterization envelopes which can be used to further reduce sampling and facilitate the selection of a remedy.
The concept of the Approved Standard Corrective Action Design (ASCADTM) has been developed at SRS and makes full use of streamlining. This concept is an innovative way of defining characterization conditions and matching them with standard environmental restoration remedies. SRS has this concept endorsed by its regulators and is using it.

GROUNDWATER MONITORING REDUCTIONS

Strategy

SRS-ER conducted an intensive review of the groundwater monitoring program required under the Resource Recovery and Conservation Act Part B Permit. The purpose of this review was to identify areas in which cost reductions could be made, while simultaneously remaining in compliance with the applicable regulatory requirements.
As a starting point, all cost elements were identified and organized into one of seven cost categories: task management, sampling, analysis, data management, report reparation, well maintenance, and DOE requirements.
The major stakeholders-the DOE customer, the South Carolina Department of Health and Environmental Control (SCDHEC), four internal Westinghouse departments, and several subcontractors-were identified and included in the process from the beginning. Through intensive discussions and negotiations, major cost savings opportunities were identified and implemented.

Streamlining

Over $2 million annually were saved by reducing the frequency of sampling and eliminating unneeded analytes. An additional $250,000 were saved by eliminating over 100 groundwater monitoring wells providing redundant information. This was done utilizing quantitative analysis of groundwater data. This statistical tool was developed as a computer algorithm by SRS with Lawrence Livermore National Laboratory and Georgia Tech. This tool allowed efficient use of groundwater data.

Cost Savings

The reduction in the frequency of sampling and the number of analytes resulted in a savings with respect to data management and report preparation. With fewer pieces of data to verify, validate, manage and report, subcontractor costs were reduced. Overall, these groundwater monitoring costs were reduced from $12 million in 1993 and $11 million in 1994 down to $7.4 million in 1995. This is shown in Table I.

Table I

INVESTIGATION DERIVED WASTES (IDW) MINIMIZATION AND TREATMENT

Strategy

IDW includes potentially contaminated environmental media such as well purge water, well pumping test and development water, drilling mud, and

soil drill cuttings. Also included in the definition of IDW is decontamination and rinse waters as well as equipment and personnel protective equipment. The SRS IDW management strategy is to minimize the quantity of IDW while cost effectively managing the IDW generated.
Two management programs are encompassed. IDW derived from contact with non-listed hazardous waste (non-listed IDW) and that derived from contact with listed waste (listed IDW).
SRS is implementing a program for the management of IDW from listed sources to achieve consistency with the Contained-In Policy. For both aqueous and non-aqueous IDW, a phased-in implementation approach is in progress. SRS treatment systems and infrastructure have been established for full implementation.
Permission from State and EPA regulators has been received to use an existing effluent treatment facility to treat mixed and radioactive purge water from monitoring wells. An approved air stripper treats non radioactive purge water.
IDW Minimization
In addition, SRS is pursuing innovative technologies and practices to reduce the volume of IDW that is generated. These innovative technologies and practices either have been or will be introduced to the EPA and the South Carolina Department of Health and Environmental Control (SCDHEC) for implementation at SRS.
Purge Water Reduction
Several methods are being evaluated to reduce the amount of purge water generated during sampling operations at SRS:
1) Micropurging uses dedicated flow sampling devices to selectively remove only water in the well directly opposite the well screen versus conventional methods of evacuating the entire column of water standing in the well and mixed in flow with stagnant water. 2) Two inch diameter wells can be used and require less water to be purged during well development and prior to groundwater sampling. SRS will continue to install two inch diameter monitoring wells where applicable. 3) The use of a casing packer to seal the upper portion of wells from the screened interval reduces the amount of stagnant water that requires purging prior to sampling. This technology is limited to four-inch diameter wells screened below the water table contaminants in concentrations above prescribed criteria.
Closed-Loop Purge Water Management
SRS is currently working with a prototype closed-loop purge water management system for aqueous IDW volume reduction. This system may eliminate the need for containerization of aqueous IDW and related transportation to a treatment system. The concept is based on capturing the water purged from a well during sampling into a collapsible tank dedicated and affixed to the well standpipe. Upon completion of the sampling event the captured water is returned to the well.
Less Invasive Drilling Techniques
SRS has conducted a successful field evaluation of a prototype device called the HydropunchTM which provides a less invasive technique for collecting groundwater samples. Direct push methods of data collection (e.g. cone penetrometer testing) and sonic drilling are being evaluated. These technologies provide real time geophysical, hydrological, and geochemical data that allow for design improvements in monitoring well networks. Improved monitoring well network designs will result in fewer

permanent wells being needed to obtain the required data, thus reducing the amount of IDW.

Cost Savings

Overall, the approval to use existing systems to treat IDW and initiatives to minimize generation had a major cost reduction of $2.5 million in FY '95 versus previous budget projections.

STREAMLINED SAMPLING APPROACHES

Strategy

SRS is now implementing streamlined sampling by scoping work plans with core team members and regulators. Every effort is made to evaluate and incorporate existing data where available. The Streamlined Approach for Environmental Restoration (SAFER) is being used at virtually all sophisticated characterization projects.

Data collection is driven by Data Quality Objectives determined by data users for future documents. There is a focus on end use determination and utilization of presumptive remedies.

The program utilizes non-intrusive sample techniques (ground penetrating radar, soil gas surveys, and magnetic surveys) and historical knowledge of known waste disposal practices at operable units. Preference exists to sample existing wells when possible to determine contaminants for groundwater and soil versus installing new wells.

Streamlining

SRS is implementing other faster characterization techniques as well. Expedited site characterization is now possible with mobile laboratories. Dynamic work plans contain built in contingencies for pre-approved decision-making. Better use of screening in-field techniques reduce laboratory costs. Use of cone penetrometer hydropunching and temporary wells reduces need for permanent groundwater wells. Appropriate analytical levels have been examined to reduce data needed.

Streamlining development of Remedial Investigations (RI) and Baseline Risk Assessments (BRA) has resulted in development of one combined RI and BRA document per operable unit. This yields savings on document production and reduced document reviews and revisions.

Cost Savings

These initiatives have combined to produce $3.35 million of savings in FY '95 versus previous budget projections. The average RI/FS cost per site is depicted in Table II.

Table II

APPROVED STANDARD CORRECTIVE ACTION (ASCADTM)

Strategy

The ASCADTM concept uses WSRC's remediation experience to develop a standard design for a specified set of contaminants and the approved remedy can be applied to any other waste site demonstrated to be within the specific envelope of contaminants. Table III graphically displays the ASCADTM process.

An ASCADTM is developed in the following way:

A single proposed plan and record of decision are planned for a grouping of similar sites.

A profile is established for a waste grouping that identifies the envelope of characterization conditions that match each proposed plan.

A proposed plan or corrective action plan is developed for the specified waste envelope.

Engineering parameters and technical requirements for the specific waste envelope are developed to ensure the record of decision will be

fulfilled for subsequent designs for remediation of waste sites that meet criteria of the specified waste envelope.

The regulators approve the proposed plan or corrective action plan for a lead site or groups/sites. Public review and comment is conducted and the record of decision is issued. Sites subsequently falling within the characterization envelope can be added to the record of decision. This concept is shown in Table III.

Table III

Streamlining

ASCADTM has the following potential benefits:

1) The overall characterization scope is streamlined by focusing on known contaminants of concern for a larger number of units 2) One treatability study workplan is developed and laboratory scale testing is conducted for a group of sites. 3) One CERCLA feasibility study, one proposed plan, and one record of decision (ROD) document are developed for a given waste unit grouping. 4) Only one SRS design review process (i.e., independent design review, value engineering study, etc.) is required. 5) One conceptual design (CD) package and one remedial design (RD) package are developed for a given waste unit grouping.

Cost Savings

The grouping of similar waste sites provides the opportunity to obtain regulator approval of a single or multiple steps of the remediation process for a given group of sites. The overall cost savings projected in 1996 and 1997 is $810,000.

CONCLUSION

SRS continues to pursue cost savings in all phases of environmental restoration. This constant improvement is necessary in an era of tightening budgets but often leads to streamlined ways of doing business that accelerate the real mission of cleanup.

8-7

PRIVATIZATION OF WASTE MANAGEMENT PROGRAMS AT THE SAVANNAH RIVER SITE

Robert E. Hottel
John R. Pickett
John R. Kosko
Larry D. MacLean
Westinghouse Savannah River Company

ABSTRACT

An aggressive effort to implement privatization initiatives at the Department of Energy's Savannah River Site (SRS) was initiated in 1991. This effort has resulted in the evaluation of potential contracts valued at $171 million, placement of $59 million in subcontracts, and capital cost savings of $142 million. This effort responds to evolving economic, political, and social changes, as well as a continuously shrinking DOE budget. Like other DOE facilities, SRS was conceived, built, and operated as a self-contained entity capable of fulfilling its mission in meeting the challenges of the Cold War. The move toward privatization required that SRS overcome the remnant Cold War barriers and required the development of cost-efficient, customer-defined products and services that also stimulated economic development in the communities surrounding SRS. This paper provides an overview of this initiative by presenting three specific case studies on waste management projects (Contaminated

Laundry Services, Mixed Waste Stabilization, and Sanitary Waste Disposal) that exemplify the successes and challenges of the SRS privatization initiative.

INTRODUCTION

SRS was constructed near Aiken, South Carolina, during the early 1950's to produce the basic materials used in the fabrication of nuclear weapons, primarily tritium and plutonium-239. Five heavy water reactors were built on the site to produce nuclear materials by irradiating target materials with neutrons. Support facilities, including two chemical separations plants, a heavy water extraction plant, a nuclear fuel and target fabrication facility, and waste management facilities were also constructed at the site.

SRS has adjusted through the years to meet the major changes in defense requirements. All five of the original SRS production reactors are shut down, a reflection of the improved U.S. relations with the former Soviet Union. While production of tritium will not be necessary for many years, recycling and reloading of tritium (due to its 12.5 year half-life) to keep the nation's supply of nuclear weapons operational is a continuing site mission. In addition to the tritium mission, SRS is developing new missions for the site. These new missions include community outreach, assistance in the economic diversification programs of the surrounding communities,and privatization.

The overall privatization effort at SRS includes four major elements:

1. Outsourcing - fixed price subcontracting of goods and services that were traditionally provided by DOE or by Management and Operating Contractor (M&O) employees,
2. Technology Transfer - the transfer of DOE developed technologies to the private sector,
3. Asset Reuse - the transfer of DOE assets through sale, lease, permit, or other means to the private sector for reuse to satisfy commercial objectives, and
4. Dual Use Commercialization - making available DOE assets through sale, lease, permit, or other means to the private sector for dual use to satisfy DOE and commercial objectives.

Outsourcing, or fixed-price subcontracting, will be the focus of this paper. Of the $59 million in subcontracts that have been placed, three of the subcontracts in the waste management area are significant, both in terms of dollar value and as examples for the rest of the DOE Complex. Those three projects are:

1. Contaminated Laundry Services: This example involves the radioactively-contaminated laundry services that were once done on the site in a forty year old facility. That service has now been contracted off the site for a capital cost saving of $13 million. As an additional benefit, a new facility is being constructed in the local community, employing local personnel and transferring additional work from an older facility. The construction of this facility was encouraged by a DOE grant that was provided as an incentive for construction in the local area.
2. Mixed Waste Sludge Stabilization: A second major effort is the stabilization of 2,500,000 liters of a mixed waste sludge from a former nickel plating and aluminum forming operation. At a cost savings of $26 million, a vendor will come on site, erect a temporary facility, vitrify the waste, and close out the existing storage tanks.
3. Sanitary Waste Disposal: SRS has traditionally disposed of all sanitary waste in landfills located on site. Due to the low volume of

sanitary waste generated, the cost per ton for disposal was very high. In addition, landfill space was being depleted, and the cost for design, permitting, and construction of a new landfill appeared prohibitive. Subcontracting for hauling and offsite disposal of SRS generated sanitary waste has resulted in a cost savings of $103 million.

For each of these examples, a brief description of the old and new way of doing business, a discussion of the obstacles faced, and a candid evaluation of results will be presented.

CONTAMINATED LAUNDRY SERVICES

Background

As part of the original construction of the Savannah River Site, a laundry for contaminated clothing and equipment, primarily respirators, was built in 1952. The laundry was located near the center of the 800 square kilometer site and operated on three shifts, seven days a week. The facility processed an average of 225 metric tons of laundry and 10,000 respirators a month.

By 1992, several motivating factors existed to support the concept of replacing the laundry facility. First and foremost, the original facility had several deficiencies, including:

- Inability to separate radioactive and non-radioactive clothing
- Lack of a waste water treatment process at the facility
- An ergonomically obsolete design
- A roof structure that prohibited installation of modern handling equipment
- Location of the facility within a secure area, requiring security clearances for workers
- Severe heat stress conditions
- Lack of modern air emissions equipment

As a consequence of these deficiencies, providing future laundry services at SRS would have required either investing in a new laundry facility, estimated to cost $13 million, or privatizing the laundry services. The privatization option was explored and selected because it met DOE objectives to reduce capital expenditures and to stimulate regional economic development by creating an opportunity for businesses to locate or expand in the area.

Description of Privatization

Outsourcing the site laundry services was one of the first SRS attempts at privatization. The success of this initiative was highly dependent on "out-of-the-box" thinking and interactions with organizations who had successfully privatized traditional DOE owned operations. These organizations included the Hanford Reservation, the Idaho National Engineering Lab, and the Oak Ridge National Lab. Several details from those interactions were applicable, but the major lesson learned was that, if the facility is to be located off-site, it is important to locate the facility in the local region.

The first approach investigated a turnkey operation, with a commercial entity building and operating a facility on SRS land that would be leased to the successful bidder. Subsequently, an alternative life cycle cost analysis, done by the M&O Contractor, showed that it would be more cost effective to contract for a laundry service with a commercial radioactive laundry. This was initially supported by the fact that Interstate Nuclear Services (INS), a commercial firm in the radioactive laundry business for thirty years, had two facilities within a reasonable vicinity of SRS. As a result of this cost analysis, Westinghouse and DOE agreed to proceed with development of a specification and a procurement package for an off-

site service, as well as a Request for Expressions of Interest that was published in the Commerce Business Daily and several regional newspapers. Prior to publication of the Request for Proposal (RFP), DOE proposed to incentivize privatization of the site laundry services by offering an award of $500,000 or 10% of construction costs (whichever was less) to the successful bidder if he were willing to construct a new facility in one of the five counties surrounding the SRS. This incentive was authorized by the FY-1994 National Defense Authorization Act, which provided for funding to stimulate local economic development. The local construction option was not mandatory; the most cost effective proposal would still be selected. Respective bidders were notified of the incentive in the cover letter issuing the RFP, with a detailed explanation of the incentive package provided at the pre-bid conference.

Evaluation of Results

The incentive for local construction of the laundry proved to be a major factor in the procurement. Even though Interstate Nuclear Services has two other facilities near SRS (one located in Columbia, SC, about 80 kilometers away), they selected the local construction option and submitted the lowest bid for the services. The contract was awarded in January, 1995. INS has obtained all necessary permits from the State of South Carolina Department of Health and Environmental Control and Aiken County and has purchased land near Interstate 20, about 30 kilometers from the SRS, for the facility. The new facility will also service commercial industry, thus contributing to the local economy by providing jobs and increased tax base for the county.

In addition to benefits to the local economy, DOE and the SRS also achieved two major benefits. The first was an estimated $13 million savings in construction of a new laundry on-site, with additional operational savings possible when the new facility becomes operational. An additional positive impact for the SRS is a 90% reduction in the amount of low-level waste generated by the old laundry facility. The old facility used respirator boxes which required disposal; the new facility will utilize respirator bags which are reusable. In addition, use of the newer commercial process for handling lint and lint filter media also reduces generation of low-level waste.

MIXED WASTE SLUDGE STABILIZATION

Background

From 1985 to 1988, nickel-plating and aluminum- forming operations were performed in the M-Area of the Savannah River Site. These operations supported four reactors operating on-site during that time and resulted in the generation of 2,500,000 liters of a plating line sludge containing depleted uranium. Treatment of this sludge, stored in double-lined tanks, is required by the site's Federal Facility Compliance Agreement and is regulated pursuant to the Resource Conservation and Recovery Act (RCRA). Original plans for stabilization of this sludge involved construction of a Filtration/Stabilization Facility for initial treatment, followed by final stabilization, in a cement form, in a proposed Mixed Waste Treatment Facility. As part of the design effort for both the pre-treatment facility and the Mixed Waste Treatment Facility, a project team was formed to address the interface between pre-treatment and final treatment. A life cycle cost study done in 1991 by the project team indicated that on-site treatment by a vendor could be significantly more cost effective than construction and operation of new facilities by the M&O Contractor.

Description of Privatization

The results of the life cycle cost study convinced site management that privatization was, by far, the preferable option. Once again, success depended upon overcoming the obstacles associated with a new, innovative process at the site. These obstacles included determination of the DOE Orders that would be applied (this was the first instance in which DOE Orders were not applied in their entirety to an on-site activity), re-negotiation of milestones with the EPA and the South Carolina Department of Health and Environmental Control (SCDHEC), and demonstration that the vendor process would meet the requirements for the resultant waste form. The first obstacle was addressed during preparation of the specification for the Request for Proposal, where agreement was reached that only "applicable" DOE Orders would be applied. During conduct of the Operational Readiness Review, all DOE Orders were reviewed, recommendations on applicability were made, and DOE concurrence obtained. Major cost savings were made through the waiver of several DOE Orders, including DOE 4700.1, "Project Management" and DOE Order 6430.1A, "General Design Criteria."

Overcoming the second obstacle, re-negotiation of the Land Disposal Restriction-Federal Facility Compliance Agreement milestone for stabilization of the sludge with the EPA and SCDHEC, required five months. The third obstacle, adequate demonstration that the final waste form would meet requirements, was overcome by requiring that the vendor successfully perform treatability studies on actual plating line sludge before award of the final contract for treatment.

Evaluation of Results

Following successful treatability studies on the plating line sludge, a contract was awarded to GTS Duratek in November of 1993. The award is a fixed-price contract, with both bonus and penalty clauses for performance. In order to expediate performance, Readiness Assessments were split into three sections (sludge transfer, construction, and operation). The Sludge Transfer Readiness Assessment was completed in May, 1995, sludge transfer was initiated in June, and the first phase of sludge transfer was completed in September, 1995. The Construction Readiness Assessment was completed in July, 1995, construction of the temporary vendor facility initiated in July, and construction was completed in January, 1996. Operation is currently scheduled for May, 1996.

In addition to the benefits of providing jobs in the private sector, the main benefit was a cost savings for DOE. The original cost estimate for the pre-treatment facility, plus the Mixed Waste Treatment Facility, plus the treatment and disposal efforts, was $46 million. The contract cost for the vendor treatment is $16 million, with infrastructure support plus disposal costs of $4 million, for a total of $20 million. This results in a cost savings of $26 million.

SANITARY WASTE DISPOSAL

Background

The Savannah River Site had always disposed of its sanitary waste in landfills located on-site. Since the sanitary waste generation rate at SRS is low (approximately 36 metric tons per day), the landfill itself is small in comparison to a commercial landfill. However, the costs associated with landfill operation are roughly the same regardless of size (e.g., the same equipment, monitoring, and close-out requirements, paperwork associated with permit compliance and renewal, etc.). Because

these fixed costs are spread over a much smaller volume, the cost per ton for disposal at a small landfill is much higher. For SRS, this means a disposal cost of approximately $1150 per metric ton, compared to a commercial cost of $55-$110 per metric ton.

Description of Privatization

Based on the high unit cost of sanitary waste disposal at SRS, the decision was made by DOE and WSRC to advertise for sanitary waste disposal services. This decision was strengthened by the fact that the existing landfill would be filled in 1998, and the design, permitting, construction, close-out, and monitoring of a new, on-site landfill would be cost prohibitive, especially for such a small operation.

In March of 1994, a Request for Proposals for Sanitary Waste Disposal Services was issued. In July of 1994, four firms responded. In September, 1994, a fixed-price contract was awarded to CDS of Charleston, Inc. CDS is a small business and utilizes the Hickory Hill Landfill in Jasper County, South Carolina, for disposal. The contract has a fixed base price for establishing a route with (currently) 311 dumpsters. A fixed price per dumpster for adding and deleting dumpsters was also established in the contract. Thus far, the price has averaged $42-$45 per metric ton of waste.

Evaluation of Results

The major impact of the change from on-site handling and disposal of sanitary waste to a privatized service for pick-up and disposal was an estimated cost savings of $103 million. This savings included the capital costs for construction of a new landfill, operating costs of the landfill, transportation costs, closure costs, and costs for 30 years of monitoring following closure.

The response from Jasper County residents concerning the landfill initiative has been very positive. Besides creating jobs for the community, the revenue assists the county with landfill operation costs and lowers taxes for the residents.

CONCLUSIONS

The three initiatives discussed above have demonstrated that the DOE can achieve significant cost savings through privatization. The major savings, roughly $140 million, in the cases shown above result from shifting the cost of construction from DOE to the private sector. Although some savings result from operating efficiencies, the majority are savings in capital costs.

Other lessons learned include:

1. The importance of properly handling the human element of privatization. The employees who are potentially affected by a privatization initiative should be informed and involved to the maximum extent possible. Where possible, employment for the affected individuals should be assured, or at least considered, in the resultant subcontract. Other options include priority transfer of affected employees to other openings on site.
2. The importance of working with local and regional economic development organizations in the private sector, and doing it as early as possible in the process. Not only will these organizations assist in recruiting companies into the area, they can often provide tax and other incentives that will make the privatization initiative even more cost effective for DOE.
3. Contrary to widely-held beliefs, not all activities are automatically performed more cost effectively in the private sector. NEPA and other

permitting activities, safety analyses, and readiness assessments are often performed more cost effectively by the M&O Contractor. This may be due to lack of experience with the DOE Orders and implementing procedures that often cannot be waived when work is done on a DOE Site. Especially in smaller companies, the required expertise, or experience with a particular state regulatory agency, may mean it is cost effective to have the M&O perform the permitting. The main point is that a valid Make-Buy Analysis is necessary before assuming that the private sector is cheaper for any and all tasks.
4. Use of existing infrastructure is usually more cost effective than having the private sector provide duplicative services. However, the rates to be charged, and the methodology of measuring the services provided, are often major obstacles to be addressed.
5. An independent technical review is essential for certain technical services that are outsourced. At the time of bid preparation and contract award, details of the process are yet to be determined and a thorough review of the completed design is essential.
6. Finally, attitudes must be changed! Probably the biggest obstacle to privatization that must be overcome are the attitudes of many DOE and M&O employees towards doing things in a new way. This culture change is slow in coming, but it must occur for privatization to truly be successful.

R.A. Shaternik
Ministry for Emergencies and Protection of the Population from the Consequences of the Chernobyl Catastrophe of the Republic of Belarus
ABSTRACT
The total area of the territory of Belarus contaminated with radionuclides amounts to 46.5 thousands km2. It is more than 20% of the whole territory. There are 3668 populated areas in it. After the Chernobyl accident Belarus has become a zone of ecological disaster. There are four special features of the Chernobyl accident:
1. Large amount of released activity from the reactor. According to the present-day knowledge this value accounts for 25.9 billions GBq. The main weight of the initial period has been a heavy burden to Belarus.
2. Large scale contamination and the prolonged period of the accidental event. The overall activity at the territory of Belarus amounts to 37 millions GBq. 137Cs, 90Sr, 239,240Pu are the main contributors to the radiation situation in Belarus. Belarus is characterized by the following data on contamination:
From 37 to 185 GBq/km2 - 29.9 thousands km2.

From 185 to 555 GBq/km2 - 10.2 thousands km2.
From 555 to 1840 GBq/km2 - 4.2 thousands km2.
More than 1840 GBq/km2 - 2.15 thousands km2.
Figure 1 presents the maps of contamination with radionuclides.
Fig. 1
3. Uneven character of contamination of territories. Even at small areas the density of contamination varies considerably. Thus, for instance, in the village Kolyban of the Gomel Region the density is in the range from 185 to 2590 GBq/km2. At the area of 1 m2 there have been the differences in the concentrations by a factor of 100. Even if dividing the portion of the soil into separate fractions with the weight up to grams, there is 10 times difference in activity between them. It is called the inhomogeneity phenomenon. There is high specific activity in the upper layer of the soil at the major part of the territory. This soil is itself the radioactive waste. Hence, these territories are the exposed radioactive waste disposal sites.
4. Radioactive contamination is combined with dangerous chemical contaminants. Thus, in Mogilev there is the high content of NO2 and H2S. Therefore, it is necessary to consider their combined effect.
The work on elimination of the consequences of the accident are carried out in accordance with the State program.
The main attention has been paid to building new populated areas. The people have been resettled on land. The large-scale industrial works on decontamination of the territories haven't been carried out. The following works have been completed:
1. Evacuation and resettlement of the population.
2. Local decontamination.
3. Disposal of radioactive wastes.
4. Division of the territory into the restriction zones.
415 populated areas in Belarus are resettled. The analysis shows that this solution cannot be considered as completely effective.
The work on decontamination of the territories, buildings and constructions bega`n in May 1986. It has been executed by subunits of chemical military troops and civil defense forces. Decontamination included local removal of the contaminated soil, demolishing the contaminated buildings and constructions.
Over the years the works on decontamination are conducted only for the most important objects: kindergartens, schools, hospitals, etc.
The main problem of Belarus is the lack of effective technologies for decontamination of the soils and large forest areas.
During 1991-1995 the clean-up of 150 objects, 360 ventilation systems has been conducted.
Depending on the density of contamination, the territory of Belarus is divided into five zones:
1. The evacuation zone - 30-kilometer zone
Sr-90 > 111 GBq/km2
Pu-238,241 > 3.7 GBq/km2
controlling and carrying regime.
2. The zone of immediate change of residence
CS-137 > 1480 GBq/km2
Sr-90 > 111 GBq/km2
Pu-238,241 > 3.7 GBq/km2
controlling and carrying regime.
3. The zone of subsequent change of residence

1480 GBq/km2 > Cs-137 > 555 GBq/km2
111 GBq/km2 > Sr-90 74 GBq/km2
3.7 GBq/km2 > Pu-238,241 > 1.85 GBq/km2
or dose > 5 mSv (0.5 rem)/year.

4. The zone with the right of changing the residence
555 GBq/km2 > Cs-137 > 185 GBq/km2
74 GBq/km2 > Sr-90 > 18.5 GBq/km2
1.85 GBq/km2 > Pu-238,241 > 0.74 GBq/km2

5. The residence zone with periodical radiation control
185 GBq/km2 > Cs-137 > 37 GBq/km2
18.5 GBq/km2 > Sr-90 > 5.5 GBq/km2
0.74 GBq/km2 > Pu-238,241 > 0.37 GBq/km2

General characteristics of contamination of Belarus are given in Table I.

Table I

The zone of evaluation of the population occupies 1987 km2. It is the territory from which the population has been evacuated in 1986. It includes forests - 877 km2, water bodies - 40.3 km2, marshes - 32.9 km2, arable lands - 940.1 km2, roads - 24 km2.

Let us consider the experience of decontamination of Belarus in details. Table II gives the list of technologies used for decontamination in Belarus. It presents the level of development of technologies.

Table II

The removal of the soil has been used for its clean-up. Both the general-purpose and special machinery have been used. The clean-up of the zones for recreation and residence is carried out in two stages.

- decontamination of the abnormal spots with high density of activity;
- decontamination of the whole area.

The exposure does rate is the criterion for carrying out the works. There are the following criteria, adopted in Belarus;

1. Territories of kindergartens, schools and hospitals 35 mR/h
2. Territories of private plots of land 40 mR/h
3. Interior rooms of kindergartens, schools and hospitals 25 mR/h
4. Working places in offices:
   - with the continued residence 50 mR/h
   - with temporary residence 200 mR/h

The internal surfaces of private buildings, kindergartens, hospitals, etc. are controlled with respect to contamination.

2.6 thousands of square kilometers have been excluded from use. 12 thousands of arable lands are exposed to erosion. Radionuclides are mainly in the upper layer of the soil at the depth from 5 to 80 cm. The value depends on the type of soil and its ploughing. In the clay soils the migration is low. In the sand soils it is faster.

The content of water soluble caesium in the soil amounts to some percents. Thus, for instance, in the Vetka area it is 3.8-5%. For the similar conditions water soluble strontium amounts to 11-26% and plutonium-239 to 2.8-9.5%. With the increase of the distance from the damaged Chernobyl reactor the fraction of mobile strontium increases too.

The average rate of migration of radionuclides in the soil amounts to 1 cm/year. It depends on the type of radionuclide. Strontium-90 has the largest rate of migration. And ruthenium-103, the least one. As to the migration rate, there is the following sequence of radionuclides; strontium-90; cerium-144; caesium-134; zirconium-95; caesium-137; ruthenium-106; ruthenium-103. Permeability of the soils to radionuclides can be presented in the following sequences: sand, sand loam, drained

peat bogs, loam. The rate increases with the increase of the moisture content.

It should be noted again, that the contamination of the soil is of uneven character. The general variation is shown in the map. The uneven character of the forests contamination has been shown earlier.

The area of the contaminated tracts of forests amounts to more than 19 thousands km2. Pine trees are the main species. They occupy 58% of forests, fir trees - 11%, birch trees - 17% and alder - 8%. The age of forests exceeding 60 years amounts to only 13%. Presently, there are the large areas of unthinned forests. The total forest reserve accounts for 804 millions m3. According to the density of contamination the damaged forests are divided into 3 types:

37-555 GBq/km2 - minor after-effects for forestry;

555-1480 GBq/km2 - restrictions for forestry;

more than 1480 GBq/km2 - prohibition of all types of felling the trees.

In 1988 the Polesje radiation forest reserve has been made. It is the most contaminated region with the total area of 1.4 thousands km2.

The main activity of the forest areas is concentrated in the forest litter. There are from 60 to 80% of radionuclides in it. It should be noted that the concentration of radionuclides in the forests is substantially larger than in meadows, marshes and other types of the territories. The largest specific activity is in the lower layers of the forest (litter, mosses, mushrooms). Bushes and grasses are the second in respect to activity. The trees have the lowest activity. In case of fires, the most active forest litter is burnt down. In addition, the radioactive particle, sorbed at the surfaces and included into the plant compositions, turn into gaseous and aerosol state. According to the data of the High Engineering Fire-Technical School, the time of life of such radioactive cloud is 7 days at the height up to 1.5 km, in the upper troposphere it is about a month and in the stratosphere, 1-5 years. New fire-extinguishing agents have been developed in Belarus. They possess high fire-retarding and fire-extinguishing efficiency. They preserve the fire curtain properties for more than 3 weeks. The consumption of the agent is 1.5-2 l/m2.

The contaminated forest has the following characteristic properties. The distribution of the activity with respect to plant organs is uneven. Table III gives the data on distribution of caesium in some parts of wood types.

Table III

Leaves and bark are the main accumulators of caesium.

Thus, it is necessary to solve the problem of processing the radioactive wastes so as to obtain the commercial wood.

Let us consider the coefficients of accumulation for various types of wood. The coefficient of accumulation is the ratio between the concentration in the wood and the concentration in the soil. Table IV presents the values of the coefficient of accumulation.

Table IV

It should be noted that there is the process of the increase of the contamination of the wood. For instance, the specific activity of the pine wood has increased twice in 1990-1992.

The volume of the wood radioactive wastes is given in Table V.

Table V

In Belarus the permissible level of contamination of firewood is 740 Bq/kg in respect to caesium-137.

There are more than 500 thousands m3 of wastes generated from pulling down wood buildings.
Therefore, there are two problems of contaminated forests. The first is connected with the decontamination of radioactive wastes, generated in the process of forestkeeping. The second one is connected with changing the contaminated forests into an ecologically safe system.
The following variants of decontamination are considered in Belarus:
1. Reducing in size and breaking up near the felling areas.
2. Collection at the open sites.
3. Thermal treatment.
Burning the wastes at the open places in forests is unacceptable owing to high activity of ash and smoke.
Presently, the possibility of using the technologies of the French company FROMATOME is considered. These technologies will make it possible to obtain clean gas and alcohol from the contaminated wood.
The feasibility study is now considered jointly between Byelorussian, Russian, Ukrainian and French specialists. The primary results are real in waste processing and changing the large forest areas into an ecologically safe system.
Another source of the radioactive waste should be mentioned. In heating the villages, 18300 tons of ash are generated yearly. Its specific activity reaches for 137CS - up to 550 KBq and for 90Sr - up to 23 KBq/kg. It can lead to the secondary contamination. Therefore, the technologies of the centralized collection of ash from the population is organized. Ash is transported to the processing and disposal sites.
The technology of immobilization of the ash wastes has been developed on the basis of phosphogypsum. It is the by-product of fertilizer production plants.
The contamination of water basins with radionuclides is defined by two regions.
The first southern region includes the basins of the Pripyat, Braginka, Vita rivers. In the initial period of the accident there have been high dose rates at the expense of short-lived radionuclides. Downstream of the Pripyat and Bragin rivers the region is characterized by contamination density of 137CS from 3.7 GBq/km2, 90Sr, 185 GBq/km2 and plutonium 3.7 GBq/km2.
The second northern region includes the basins of the Dnepr, Sozh, Iput, Besed rivers. The radiation situation has been formed here mainly at the expense of atmospheric precipitations. 137Cs contamination density reaches up to 5550 GBq/km2, 90Sr to 37 GBq/km2.
Immediately after the accident the permissible concentration (4.10-10 Ci/l in the downstream water of the Pripyat river has been considerably exceeded for the limited contingent of population but at the end of May 1986 the concentration had been reduced to 10-10 Ci/l.
The average annual 137Cs concentration in the Pripyat, Dnepr, Sozh, Iput rivers is lower than the permissible levels and does not exceed the Republican control levels (Republican control levels are 5.10-10 Ci/l).
If in the initial period of the accident the contamination of the water has been determined by the deposition of the radioactive aerosols on the water surface, later the level of contamination has been determined by wash-off from the watershed surface, exchange with bottom sediments.
According to the data of the State Department for Hydrometeorology, the total wash-off of 137Cs by the five above rivers has amounted to: 22900

GBq in 1987; 12580 GBq in 1988; 7030 GBq in 1989; 3034 GBq in 1990; 2664 GBq in 1991.
The main contribution has been obtained at the Sozh river. Its wash-off has accounted for 10360 GBq in 1987; 5180 GBq in 1988; 2220 GBq in 1989; 925 GBq in 1991.
The analysis of the wash-off characteristics has shown that in 1991 the activity has been determined by caesium-137. The presence of anomalies should be noted. Thus, in the Kulazhin village on the shore of the Nesvich river the contamination with strontium does not exceed the contamination with caesium and amounts to 1130 GBq/km2. The substantial contribution from 106Ru and 144Cs is seen (225 and 52 GBQ/km2, respectively). In this area the increase of density of contamination has been observed: 5660 GBq/km2 in March; 19280 GBq/km2 in October. Similar phenomena have been seen in other areas.
The main fraction of activity is in the bottom sediments. They have a specific activity much higher than water. It amounts to 40000-700 Bq/kg and 4000-10 GBq/kg for 137Cs and 90Sr, respectively.
There are also the seasonal changes.
The works on protection from the water transport of radionuclides and decontamination of bottom sediments are not carried out in the Republic.
Large works on decontamination of the industrial equipment are conducted. 390 ventilation systems have been decontaminated. The total cleaned-up area amounts to 57 thousands m2. More than 1300 pieces of industrial equipment are subject to decontamination.
In Table VI the detergents for decontamination of such systems are given.
Table VI
The works on creation of the pastelike compositions for decontamination of unpainted surfaces are carried out. They can decontaminate 97% of 137Cs and 95% of 90Sr. In the process of decontamination liquid and solid radioactive wastes are generated.
In the Institute of Radioecological Problems of the Academy of Sciences of Belarus two installations have been designed for treatment of liquid radioactive waste.
The first installation is operated on the principle of chemical co-precipitation followed by separation of solid and liquid phases.
The second installation takes the evaporation of rotatable liquid flow as the basis.
The process of volumetric evaporation is carried out in this apparatus. Liquid is preheated and then the evaporation of whirled liquid occurs, when pressure is reduced. It should be noted that such eddy evaporator is the separator at the same time. It decontaminates liquid radioactive wastes of any composition.
Figure 2 gives the basic elements of the installation for processing liquid radioactive wastes. The installation embodies the following principle:
Liquid is heated and conveyed by the tangential channel into the evaporation chamber. On the certain radius of rotation liquid cones to the boil. Vapor bubbles move to the axis of the periphery. The main technical characteristics of the installation are as follows:
Fig. 2
1. Initial temperature of liquid radioactive wastes is 278-298 K.
2. Capacity of 0.05 - 0.01 kg/sec.
3. Operating conditions for pH are not specified.
4. Decontamination factor is 105.

Let us consider the problems of sewage waters. The selective investigation of the radiation situation of the sewage works have been conducted. In the fields of filtration of the Slavgorod town the specific activity of 60000 Bq/kg has been found out.

It should be noted that the state of radionuclides in the fields of filtration differs from that in the soil. The mobile form of 137Cs amounts to 21-46% and 90Sr to 68-85%.

The preliminary works on decontamination of sewage works are carried out. In 1986-1988, 69 interim repositories have been created for disposal of radioactive wastes. The works on determination of radiation danger of these repositories are conducted. The system of radiation monitoring has been created. The observation wells have been made around the repositories. There is no danger now. Mathematical modeling of Belarus and Sweden specialists have shown that in the future the ingress of strontium into the aquifer is possible. There are seven repositories for disposal of the radioactive wastes generated in the process of decontamination at the territory of the zone of changing the residence. The volume of each of them is 30-50 thousands m3. presently, 120 thousands m3 are without backfilling. 120 thousands m3 of repositories will be constructed to 2000.

Work on selection of sites for perspective disposal have been carried out. The principles and the methods of shallow ground and surface repositories have been worked out. Six types of sites have been assigned, ranging from favorable to useless. Ecologically safe sites have been found. The following areas have been chosen for radioactive waste repositories:

The Gomel Region:

- Narovlya area - "Karpovichi" sites;
- Khojniki and Bragin area - "Babchin" - 4 site;

The Brest Region:

- Stolin area - "Olmyanskaya Koshara" site;
- Luninets area - "Dobraya Volya" site.

Figure 3 shows the location of the repositories on the map. The codes of practices have been worked out for carrying out the work on decontamination. They determine the sequence and technologies for work on decontamination, demolition of buildings and waste management.

Fig. 3

The works on decontamination need enormous expenditures. In the laboratory of Radioecological Problems of the Institute of Radioecological Problems of AS B, complex methods have been developed. They determine the expediency of carrying out the work. The cost-benefit analysis is the basis of the methods.

Figure 4 gives the schematic diagram of the program of evaluation f the efficiency of decontamination.

Fig. 4

With the help of the program the following operations can be made:

1) Evaluation of the efficiency of decontamination of soils and the ground;
2) Comparison with the alternative technologies and the choice of the optimal one;
3) Comparison of the optimal technology of decontamination of soils and the ground with the alternative methods of rehabilitation and the choice of the best variant.

The evaluation of the efficiency of the technologies of decontamination of soils and the ground has been carried out according to the criterion:

$$Ed = R + MS = Cd \max,$$

where Ed - efficiency of decontamination, roubles/km2;
R - reduction of the integral detriment to health of the population as a result of decontamination;
MS - Additional production of products attributed to the decontamination of the territory, roubles/km2;
Cd - cost of decontamination, roubles/km2,
DF - final detriment after decontamination;
Dp - detriment attributed to exposure to radiation of operational personnel.

Table VII presents the economic efficiency of decontamination of agricultural lands with the help of removal of the soil by deep ploughing to the depth of 70 cm.

Table VII

Removal of the soil is more efficient than deep ploughing.

Decontamination has the positive efficiency only with utilization of wastes and conversion into energy. In addition, the economic effect is smaller by a factor of thousand than the removal of the soil.

On the basis of the above the following conclusions should be made:

1. In Belarus the tactics of observation and changing the residence have been mainly carried out. The large-scale decontamination of the territories has not been carried out.
2. The scales of decontamination are to be determined by the cost-benefit analysis methods. The criteria of the density of decontamination, dose rates, etc., are only the internal parameters of the methods. They do not determine the expediency of the decontamination works.
3. Taking into account high cost of decontamination, it is advisable to create the international standard computational programs for "cost-benefit" analysis.
4. It is necessary to unite international efforts for development of the efficient technologies on clean-up of the soil, forest areas and water systems.
5. It is advisable to create the international data base on technologies and methods of decontamination of large territories.

Phase 1:

Creation of Simple Operational Data Base Able to be Connected to GIS Describing Currently Available Information on Radiation Legacy of the Former USSR

Phase 2:

Public Accessible Prototype Data System Including Radiation Legacy Data Base Linked to GIS

ABSTRACT

The objective of the Project is to create a public accessible database linked to geographical information system (GIS) that will describe availableinformation on the radiation legacy of the former Soviet Union (FSU). This system will be developed so as to aid policy makers in two principle areas:

1. identify and set priorities on radiation safety problems and
2. provide guidance for the development of technically, economically, publicly, and institutionally sound policies to reduce the impact of radioactively contaminated sites.

Over the past 50 years, vast quantities of radioactive waste (RW) and numerous radioactively contaminated sites resulting from the production of nuclear weapons and civilian use of nuclear energy have accumulated in several countries. Although there are studies and cooperative efforts on aspects of this overall issue, there has been no systematic, comprehensive and interdisciplinary effort to exchange information and coordinate activities, to achieve technically sound and cost effective management, and cleanup of the RW.

The aim of this project is to provide usable information that can aid to make decisions for radiation hazard management. It will aid also in conducting risk estimate studies, analyzing the transboundary and transjurisdictional aspects of waste and spent fuel transportation, determining future land uses, and evaluating radionuclide material flows through the environment.

In accordance with the funding directives of the ISTC, this project has been separated into two phases, the first phase will last one year and is being carried out now.

Phase 1 consists of :

the development of the methodology necessary for a systems approach to the creation of the database and GIS technology;
collection and analysis "first order" data;
determination of the computer application methodologies;
development of a simple operational prototype data system linked to 2 or 3 GIS examples.

Phase 2 will consist of :
an evaluation of the completeness of data collected during Phase 1;
collection and analysis additional, "second order" data including socio- institutional, geographic, demographic, and climatic characteristics allowing to develop a public accessible data base and GIS;
development of the map blocks as GIS components;
creation a public accessible data system including data base and GIS on radiation legacy of the former USSR.

DESCRIPTION OF THE DATA

The data are separated into three classes, rated according to its accessibility: sector-overview data, first-order data, and second-order data.

Sector-overview data represents a review of information about radioactive waste accumulated and about the plans for nuclear materials management available in organizations taking part in this project. Each participating organization have prepared an overview for its sector of professional activity; for example, nuclear test sites, civilian NPPs, reprocessing plants, etc. General Sector Overview based on materials by participating research groups in participating institutions (along the whole project) is prepared and delivered to ISTC.

First-order data represents

1) physical, chemical, technical and general characteristics of the facilities of interest, and

2) socio-institutional data

The data from facilities are based on information currently available in organizations participating in the project and include specific archives, data published in the literature as well as data contained in existing local databases.

Socio-institutional data are based on polls that were conducted by INTEST in 1993 in regions of major social anxiety and concerns about local radioactive problem (Urals, regions around Chernobyl, Russian North).

Second-order data embraces

1) additional information on the physical, chemical, technical and general characteristics that will be considered as necessary after evaluation of the completeness and quality of the first-order data (Sources of this additional information will be unclassified archives and additional calculations and verification of the models used for quantitative estimations.),

2) data on the socio-institutional characteristics pertinent to the radioactive objects and not covered during Phase 1, and

3) data on geographical, geological, demographical, and climatical characteristics that permit the database collected during Phase 1 to be organized into a Geographical Information System (GIS).

The public accessible prototype database and GIS will be developed on computer centers located at VNIICHT and RRC "Kurchatov Institute". All data that is collected and stored on this system will be accessible to the public via the networks RELCOM / EUNET / INTERNET.

EXPECTED RESULTS

A public accessible prototype database system on the FSU radiation legacy. The database will include:

- available physical, chemical, technical, and general information about civil and military objects of the nuclear fuel cycle, obtained from all areas of the FSU; and
- socio-institutional, geographic, geologic, demographic and climatic characteristics of civil and military objects of the nuclear fuel cycle and surrounding areas.

A computerized GIS linked to public accessible prototype database system on the FSU radiation legacy. GIS will include three categories of multilayer thematic maps:

- Survey (3 semi-global for the whole area of the FSU);
- Highlights (20 regional with description of radiation situation);
- Radioecology (20 local with description of radiatively dangerous objects).

A video information about some objects of radiation legacy

SCOPE OF ACTIVITIES

To reach the goals of identification and setting priorities on radiation safety problems, analytical tools must be developed. The proposed study will include the following three activities:

Activity 1: Methodology of Systems Approach to Database Creation

The main part of this activity have been carried out in the first phase of the project (collection of key reports and information about radiation legacy of the FSU, descriptions of the most serious problems caused by this legacy, as well as current and expected efforts to cope with them, documentation and examination of existing methodologies and experience with assessment data needs and data base creation).

The outcome of this activity is the development of the version of data base structure necessary for the Activity 2 realization.

Activity 2: Data Collection and Analysis

This activity will entail the collection and verification of the data for providing a review of extent and seriousness of radiation problems left by the cold war and accidents at nuclear facilities of the FSU, as well as those caused by its disintegration.

The basic idea is to describe the radiation risk sources: potential radioactive releases, contained radioactive wastes, and contaminated areas. The sources must be grouped into five categories: military, civilian, front end of the fuel cycle, back end of the fuel cycle, and non-reactor radioactive waste burial sites.

As a first step of the Project first phase, the Sector Overview has been prepared on what data are currently and potentially available from the Russian Federation and the other NIS. Then the process involve the collection of "easily" available data ("first order data"), finalized by the creation of a simple operational data base.

The second phase will start from the evaluation completeness and quality of the data collected during the first phase. The purpose is to identify gaps in the data and provide this information together with the requirements for additional data ("second order data") collection.

The second phase will result in the collection of the second order data and their analysis.

Activity 3: Generation of Public Accessible Prototype Data System

The collected and verified data will be organized in the computerized public accessible data system.

This activity involves the following steps:

The data base on the radiation legacy of the FSU is being built on a number of existing data bases that are already in use in the NIS or in the phase of creation.

An analysis is being made of computer methodologies currently used for these specific data bases.

The task to determine which GIS methodologies might be effectively linked to the data base must be done. This is followed by the development and demonstration the feasibility and capabilities of the conceptual design.

Realization a conceptual design of a public accessible computer-based data system of the radiation legacy of the FSU by multilayer map blocks development and input the collected data into these blocks will be the ultimate goal of the Project second phase.

TECHNICAL APPROACH AND METHODOLOGY

Nineteen main sectors of the nuclear fuel cycle, both civilian and military, are framed for this project and are investigated by participating institutions, which have responsibility for collecting data on the radiation legacy. Each institution obtain and analyze the information in those sectors closely connected to its professional activities.

The database describes the types and characteristics of objects containing radioactive materials, physical, chemical and technical characteristics as well as geographical, geological and socio-institutional data on the radiation legacy. The data will be organized in a public accessible computerized database which will be linked to a multilayer Geographic

Information System (GIS) consisting of semi-global, regional and local map blocks.

The semi-global block represents a survey GIS saturated by data which give an overview of radiation legacy objects arrangement. The regional blocks represent a highlights of the FSU areas containing the significant radiation sources. Among these the first line constitute the regions as follows: Kola Peninsula; Novaya Zemlya; Tomskaya Oblast; Urals; Center of Russia European Part (at first areas exposed by Chernobyl accident pollutions and NPPs location sites); Semipalatinsk; North-West (Lithuania, Leningrad Oblast); Pacific Navy.

The local blocks will give a detailed radioecologic picture for sites where the major amounts of radionuclides are arranged.

The map blocks being created will be saturated by factographic (attributive) data collected during the first and second phases of Project efforts.

The project activities will be carried out in nineteen Participating Institutions of the Russian Federation:

ABSTRACT
Phase 1:
Creation of Simple Operations Data Base Able to be Connected to GIS Describing Currently Available Information on Radiation Legacy of the Former USSr
Phase 2:
Public Accessible Prototype Data System Including Radiation Legacy Data Base Linked to GIS

INTRODUCTION

The objective of the Project is to create a public accessible database linked to geographical information system (GIS) that will describe

available information on the radiation legacy of the former Soviet Union (FST). This system will be developed so as to aid policy makers in two principle areas:

1. Identify and set priorities on radiation safety problems and
2. Provide guidance for the development of technically, economically, publicly, and institutionally sound policies to reduce the impact of radioactively contaminated sites.

Over the past 50 years, vast quantities of radioactive waste (RW) and numerous radioactively contaminated sites resulting from the production of nuclear weapons and civilian use of nuclear energy have accumulated in several countries.

Although there are studies and cooperative efforts on aspects of this overall issue, there has been no systematic, comprehensive and interdisciplinary effort to exchange information and coordinate activities to achieve technically sound and cost effective management, and cleanup of the RW.

The aim of this project is to provide usable information that can aid to make decisions for radiation hazard management. It will also aid in conducting risk estimate studies, analyzing the transboundary and transjurisdictional aspects of waste and spent fuel transportation, determining future land uses, and evaluating radionuclide material flows through the environment.

In according with the funding directives of the ISTC, this project has been separated into two phases, the first phase will last one year and is being carried out now.

Phase 1 consists of:

the development of the methodology necessary for a systems approach to the creation of the database and GIS technology;

collection and analysis "first order" data; - determination of the computer application methodologies;

development of a simple operational prototype data system linked to 2 or 3 GIS examples.

Phase 2 will consist of:

an evaluation of the completeness of data collected during Phase 1;

collection and analysis additional, "second order" data including socio-institutional, geographic, demographic, and climatic characteristics allowing to develop a public accessible data base and GIS;

development of the map blocks as GIS components;

creation of a public accessible data system including data base and GIS on radiation legacy of the former USSR.

DESCRIPTION OF THE DATA

The data are separated into three classes, rated according to its accessibility: sector-overview data, first-order data, and second-order data.

Sector-overview data represents a review of information about radioactive waste accumulated and about the plans for nuclear materials management available in organizations taking part in this project. Each participating organization has prepared an overview for its sector of professional activity; for example, nuclear test sites, civilian NPPs, reprocessing plants, etc. General Sector Overview based on materials by participating research groups in participating institutions (along the whole project) is prepared and delivered to ISTC.

First-order data represents

1) physical, chemical, technical and general characteristics of the facilities of interest, and
2) socio-institutional data
The data from facilities are based on information currently available in organizations participating in the project and include specific archives, data published in the literature as well as data contained in existing local databases.
Socio-institutional data are based on polls that were conducted by INTEST in 1993 in regions of major social anxiety and concerns about local radioactive problem (Urals, regions around Chernobyl, Russian North).
Second-order data embraces
1) additional information on the physical, chemical, technical and general characteristics that will be considered as necessary after evaluation of the completeness and quality of the first-order data (Sources of this additional information will be unclassified archives and additional calculations and verification of the models used for quantitative estimations.)
2) data on the socio-institutions characteristics pertinent to the radioactive objects and not covered during Phase 1, and
3) data on geographical, geological, demographical, and climatical characteristics that permit the database collected during Phase 1 to be organized into a Geographical Information System (GIS).
The public accessible prototype database and GIS will be developed on computer centers located at VNIICHT and RRC "Kurchatov Institute." All data that is collected and stored on this system will be accessible to the public via the networks RELCOM / EUNET / INTERNET.
EXPECTED RESULTS
1) a public accessible prototype database system on the FSU radiation legacy. The database will include:
  available physical, chemical, technical, and general information about civil and military objects of the nuclear fuel cycle, obtained from all areas of the FSU; and
  socio-institutional, geographic, geologic, demographic and climate characteristics of civil and military objects of the nuclear fuel cycle and surrounding area.
2) a computerized GIS linked to public accessible prototype database system on the FSU radiation legacy. GIS will include three categories of multilayer thematic maps:
  Survey (3 semi-global for the whole area of the FSU);
  Highlights (20 regional with description of radiation situation);
  Radioecology (20 local with description of radiatively dangerous objects).
3) a videoinformation about some objects of radiation legacy
SCOPE OF ACTIVITIES
To reach the goals of identification and setting priorities on radiation safety problems, analytical tools must be developed. The proposed study will include the following three activities:
Activity 1: Methodology of Systems Approach to Data Base Creation
The main part of this activity has been carried out in the first phase of the project (collection of key reports and information about radiation legacy of the FSU, descriptions of the most serious problems caused by this legacy, as well as current and expected efforts to cope with them, documentation and examination of existing methodologies and experience with assessment data needs and data base creation).

The outcome of this activity is the development of the version of data base structure necessary for the Activity 2 realization.

Activity 2: Data Collection and Analysis

This activity will entail the collection and verification of the data for providing a review of extent and seriousness of radiation problems left by the cold war and accidents at nuclear facilities of the FSU, as well as those caused by its disintegration.

The basic idea is to describe the radiation risk sources: potential radioactive releases, contained radioactive wastes, and contaminated areas. The sources must be grouped into five categories: military, civilian, front end of the fuel cycle, back end of the fuel cycle, and non-reactor radioactive waste burial sites.

As a first step of the Project first phase, the Sector Overview has been prepared on what data are currently and potentially available from the Russian Federation and the other NIS. Then the process involves the collection of "easily" available data ("first order data"), finalized by the creation of a simple operational data base.

The second phase will start from the evaluation completeness and quality of the data collected during the first phase. The purpose is to identify gaps in the data and provide this information together with the requirements for additional data ("second order data") collection.

The second phase will result in the collection of the second order data and their analysis.

Activity 3: Generation of Public Accessible Prototype Data System

The collected and verified data will be organized in the computerized public accessible data system.

This activity involves the following steps.

The data base on the radiation legacy of the FSU is being built on a number of existing data bases that are already in use in the NIS or in the phase of creation.

An analysis is being made of computer methodologies currently used for these specific data bases.

The task to determine which GIS methodologies might be effectively linked to the data base must be done. This is followed by the development and demonstration of the feasibility and capabilities of the conceptual design.

Realization of a conceptual design of a public accessible computer-based data system of the radiation legacy of the FSU by multilayer map blocks development and input of the collected data into these blocks will be the ultimate goal of the Project's second phase.

TECHNICAL APPROACH AND METHODOLOGY

Nineteen main sectors of the nuclear fuel cycle, both civilian and military, are framed for this project and are investigated by participating institutions, which have responsibility for collecting data on the radiation legacy. Each institution will obtain and analyze the information in those sectors closely connected to its professional activities.

The database describes the types and characteristics of objects containing radioactive materials, physical, chemical and technical characteristics as well as geographical, geological and socio-institutional data on the radiation legacy. The data will be organized in a public accessible computerized database which will be linked to a multilayer Geographic Information System (GIS) consisting of semi-global, regional and local map blocks.

The semi-global represents a survey GIS saturated by data which give an overview of radiation legacy objects arrangement.
The regional blocks represent highlights of the FSU areas containing the significant radiation sources. Among these the first line constitute the regions as follows: Kola Peninsula; Novaya Zemlya; Tomskaya Oblast; Urals; Center of Russia European Part (at first areas exposed by Cernobyl accident pollutions and NPPs location sites): Semipalatinsk; North-West (Lithuania, Leningrad Oblast); Pacific Navy.

ABSTRACT
The DOE Spent Nuclear Fuel Program has made considerable progress over the past year in defining a path forward for the management and disposition of DOE-owned spent nuclear fuel. Key elements of the program strategy include 1) assuring safe existing conditions, 2) achieving safe interim storage, and 3) preparing for ultimate disposal in a geologic repository. DOE-owned spent nuclear fuel is spread throughout the DOE Complex in a variety of storage modes and conditions which have been factored into an integrated program management strategy. However, legal challenges and federal and state agreements, National Environmental Policy Act (NEPA) documentation and legislative initiatives have the potential to influence the future direction of the program strategy. Examples include: the outcome of ongoing or new litigation including consent orders; NEPA documentation and records of decision concerning DOE-owned spent fuel storage, processing, and ultimate disposition; and proposed legislation that may significantly affect the management of DOE-owned spent nuclear fuel. This paper seeks to examine the impacts of these factors and other emerging programmatic issues on the current and future course of the program.

INTRODUCTION

The December 1994 DOE-Owned Spent Nuclear Fuel Strategic Plan (1) (to be updated in 1996) articulates the mission, vision, objectives and strategies for the management of DOE-owned spent nuclear fuel spent nuclear fuel (SNF). The DOE Spent Nuclear Fuel Program has made considerable progress over the past year in further defining a path forward for the management and disposition of DOE-owned SNF. Key elements of the program strategy include 1) assuring safe existing conditions, 2) achieving safe interim storage, and 3) preparing for ultimate disposal of approximately 2,800 MTHM of DOE-owned spent nuclear fuel in a geologic repository. DOE-owned spent nuclear fuel is spread throughout the DOE Complex in a variety of storage modes and conditions which have been factored into an integrated program management strategy. This strategy is outlined in the Programmatic Spent Nuclear Fuel and Idaho National Engineering Laboratory Waste Management and Environmental Restoration and Waste Management Programs Environmental Impact Statement Record of Decision (2) which identifies "regionalization by fuel type" as the management alternative to be implemented for spent nuclear fuel in the DOE Complex.

Specifically, aluminum-clad spent fuel will be managed at the Savannah River Site and stainless-steel/zircaloy-clad spent fuel, with the exception of the production fuel at the Hanford Site, will be managed at the Idaho National Engineering Laboratory. These fuels would be stored in existing facilities with modifications and upgrades as needed until new interim dry storage facilities become operational. Ultimately, DOE-owned spent fuel would be transferred to a permanent geologic repository unless otherwise dispositioned. Current agreements with States and Consent Orders have been accounted for in the program strategy. Further details of the DOE spent nuclear fuel program strategy are articulated in both the Interim Storage Plan (3) and Program Plan (4) issued by the Office of Spent Fuel Management in November 1995.

Further programmatic guidance concerning the implementation of the "regionalization by fuel type" strategy is found within the DOE-Owned SNF Program Plan. This document is supported by other publications, such as the DOE-Owned SNF Interim Storage Plan, which provide greater detail concerning the various elements of implementation. The storage plan acts to integrate those national and site-specific plans needed to effectively manage DOE-owned SNF during its interim storage. The scope of the DOE-Owned SNF Interim Storage Plan includes the integration of planning and implementation activities associated with the handling, conditioning, storage, and transport of DOE-owned SNF.

Despite the establishment of a clear waste management strategy and set of objectives as announced in the mentioned plans, the Department continues to recognize the increasingly dynamic climate in which future waste management policy decision shall be made and to identify influences upon these established implementation activities. This paper seeks to examine the implications of a number of influences, specifically, pertinent political, legal, and legislative initiatives upon DOE's spent fuel program strategy. These influences include: the outcome of ongoing or new litigation and State and Federal government agreements concerning spent nuclear fuel; proposed National Environmental Policy Act (NEPA) documentation and Records of Decision concerning DOE-owned spent fuel storage, processing, and ultimate disposition; and legislation that may significantly affect the timing of repository availability.

LEGAL ACTIONS/STATE AND FEDERAL GOVERNMENT AGREEMENTS

The key agreements impacting the DOE spent fuel program include the Hanford Tri-Party Agreement, the DOE/Navy/Idaho Agreement on Spent Fuel and Nuclear Waste, and the DOE/Public Service of Colorado Agreement (In Principle) to Manage Spent Fuel at Fort St. Vrain. Each of these agreements sets forth terms and conditions that affect the manner in which DOE is able to manage its spent fuel in the complex.

The Hanford Tri-Party Agreement (5)

Over the past few years, the mission of the Hanford Site has changed from nuclear material production to environmental cleanup. The framework for this cleanup effort is outlined in the Hanford Federal Facility Agreement and Consent Order, commonly referred to as the Tri-Party Agreement signed by the Environmental Protection Agency (EPA), the Washington State Department of Ecology, and DOE. The Hanford Site manages the largest amount of DOE-owned spent nuclear fuel (by weight) with a current inventory of approximately 2,133 MTHM, representing approximately 81% of the Department's entire spent nuclear fuel inventory, the vast majority of which is production fuel.

In the early years of the Hanford Site, a number of onsite facilities were utilized for the processing and storage of spent production fuel. From the early 1970's through 1987, PUREX, a major processing facility, remained off-line while undergoing necessary refurbishment and awaiting restart. During this time, the K Basins, originally designed for the temporary storage of K-Reactor fuel, served as temporary storage for spent production fuel generated at the now inactive N-Reactor. Following PUREX's return on-line in 1988, much of the N-Reactor spent fuel was processed as planned. However, a 1992 Department action permanently deactivating the PUREX facility left approximately 2,100 MTHM of N-Reactor spent production fuel in the K Basins with no immediate strategy for removal.

The Tri-Party agreement set milestones and target dates to encapsulate fuel and sludge from K Basin East, treat and dispose of contaminated water, and to remove all fuel and sludge from the K-Basins by 2002. In the Department's strategy, the completion date for the removal of spent production fuel from the K Basins is scheduled for December 1999. The fuel will then be conditioned, repackaged, and stored in a dry storage area within the planned Canister Storage Building at the Hanford Site.

DOE/Navy/Idaho Agreement on Spent Fuel and Nuclear Waste (6)

Following several months of intensive negotiations, the Departments of Energy and Navy reached agreement with the State of Idaho regarding spent fuel and radioactive waste issues at the Idaho National Engineering Laboratory. The terms of the agreement were incorporated into a Consent Order bringing long-standing litigation to a close. Negotiations were driven by a set of guiding principles and interests on the part of the Federal government and the State. DOE's interests centered on continued national security, future environmental protection, effective investment of public funds, and equitable treatment of other concerned states by the DOE and the Department of Navy. As for the State of Idaho, key negotiation interests included obtaining firm commitments by the Federal government regarding dates for the removal of all spent nuclear fuel and other wastes from Idaho, acceleration of environmental restoration at INEL, and economic investment in southeastern Idaho. It should be noted that DOE and the Navy negotiated in good faith and entered into this

agreement with the State of Idaho for the explicit purpose of preserving U.S. national security interests.

Under the agreement, the Navy is to resume spent fuel shipments to Idaho immediately, up to a total of 575 Navy fuel shipments (55 MTHM) through the year 2035. Prior to December 31, 2000 , the receipt of DOE-owned spent nuclear fuel shipments at the Idaho National Engineering Laboratory shall be contingent upon the United State's adoption of a policy to manage spent nuclear fuel from foreign research reactors to support U.S. nuclear weapons nonproliferation objectives. The number of shipments would be limited to 61 foreign research reactor spent fuel shipments. Following the year 2000, no more than 55 MTHM of DOE-owned spent fuel, approximately 497 truck shipments, would be made to Idaho. Furthermore, the constraint on receipt of only essential DOE shipments at the Idaho National Engineering Laboratory shall continue only until such time as a repository or interim storage facility outside of Idaho is accepting spent nuclear fuel from INEL.

As part of the settlement, the State of Idaho has agreed to support fully DOE's efforts to obtain the permits and approvals necessary to meet its initiatives under the Agreement, and in any future third party lawsuits brought against the Government concerning the adequacy of the Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement and Record of Decision.

In return for these shipments to INEL, DOE has made a number of commitments to the State of Idaho. Failure to meet these commitments would result in suspension of DOE shipments. Key DOE commitments include:

Begin removal of transuranic waste from INEL by April 30, 1999, with complete removal by 2018

Complete removal of all spent fuel from INEL by 2035

Complete treatment of all calcined high-level waste at INEL by 2035

A mixed waste treatment facility for transuranic and alpha-contaminated mixed low-level waste at INEL operational by 2003

Transfer of all spent fuel at INEL from wet storage to dry storage by 2023

Transfer equivalent numbers of spent fuel shipments between Savannah River Site and INEL annually

Establish INEL as DOE's lead laboratory for spent fuel research and development

Over the next five years, DOE estimates the cost of its initiatives under the Agreement to be about $200 million; Navy initiatives are estimated at $110 million. In addition, DOE will provide Idaho with $30 million to assist in the diversification of the southeastern Idaho economy. If the Government fails to remove all the spent nuclear fuel at INEL from Idaho by January 1, 2035, the Government is obligated to pay (pending Congressional appropriations) $60,000 a day (unescalated) to the State.

DOE/Public Service of Colorado Agreement (In Principle) to Manage Spent Fuel at Fort St. Vrain (7)

Under the Idaho Agreement, DOE agreed not to ship Fort St. Vrain spent nuclear fuel from Colorado to INEL unless a permanent repository or interim storage facility outside of Idaho is opened and accepting spent nuclear fuel from INEL and the shipments are needed for the purpose of treating the spent fuel to make it suitable for off-site storage or disposal. As a result, DOE and the Public Service of Colorado have executed an agreement in principle for DOE to take title of the spent

fuel from the Fort St. Vrain nuclear power plant. Under this agreement, DOE will pay the Public Service of Colorado $16 million for the Independent Spent Fuel Storage Facility, plus future operating and maintenance costs. Approximately 1,464 spent fuel elements (about the volume of a railroad boxcar) are in storage. Once the agreement becomes final, and the transfer of licensing and closure of other legal matters is complete, DOE will take title to the spent fuel and transfer it off-site when DOE interim storage or the repository becomes available.

In 1965, DOE signed a contract to take the fuel and ship it to INEL for storage. However, strong opposition from the State Legislature of Idaho and Indian tribes have continually precluded DOE from doing so. Fort St. Vrain shut down in 1989. DOE saves approximately $2.0 million annually at INEL by consolidating spent nuclear fuel storage into space originally reserved for the Fort St. Vrain spent nuclear fuel.

NATIONAL ENVIRONMENTAL POLICY ACT

DOCUMENTATION AND DECISIONS

The type and nature of activities in implementing the DOE spent nuclear fuel program strategy are affected by decisions made under related National Environmental Policy Act documents. As discussed earlier, the framework for the DOE-owned spent-nuclear fuel program strategy is the Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Environmental Impact Statement (SNF&INEL PEIS) Record of Decision issued on June 1, 1995. The SNF&INEL PEIS Record of Decision stated that DOE aluminum-clad spent nuclear fuel would be managed at the Savannah River Site and other DOE spent nuclear fuel will be transported and managed at the Idaho National Engineering Laboratory. The exception to this management regime is the Hanford Site, where all production fuel would continue to be managed onsite. The shipment limitations contained in the Agreement with the State of Idaho will cause some perturbation in carrying out the Record of Decision; in particular, it is likely that non-production spent nuclear fuel at the Hanford Site, with the exception of sodium-bonded fuel, will remain at the Hanford Site for continued storage.

DOE arrived at a key policy decision with respect to the ultimate disposition of DOE-owned spent nuclear fuel in developing the SNF&INEL PEIS Record of Decision. Specifically, some or all of DOE-owned spent nuclear fuel that is not otherwise dispositioned (i.e., chemically separated, with the high level waste being converted into a vitrified waste form for repository disposal), is authorized for disposal in the first repository. This is subject to the total quantity of DOE spent nuclear fuel and high-level waste not exceeding ten percent of the first repository capacity limit of 70,000 metric tons of heavy metal, and meeting the DOE-owned spent fuel acceptance criteria.

The SNF&INEL PEIS Record of Decision provides an important framework from which to manage DOE-owned spent fuel. In addition, other ongoing DOE NEPA documentation is under development on related spent fuel management activities. These include:

The Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (8)

Reducing the threat of the proliferation of nuclear weapons is one of the foremost goals of the United States. Proper management of spent nuclear fuel from foreign research reactors supports this goal, since much of

this spent fuel contains highly-enriched uranium which can be directly used in simple nuclear weapons. The proposed action being considered in the Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel (FRR SNF EIS) is for DOE and the Department of State to jointly adopt a policy to manage spent nuclear fuel from foreign research reactors. Only spent fuel containing uranium enriched in the United States would be covered by the proposed action.

It is unclear at this writing what the Department's preferred alternative will be. Up to 19.2 MTHM of foreign research reactor spent nuclear fuel could be accepted and managed in the United States for national security purposes or managed at one or more overseas facilities under certain conditions. If managed in the United States, the spent nuclear fuel would be stored at the Savannah River Site and/or at INEL. A portion of the foreign research reactor spent nuclear fuel could be chemically separated at the Savannah River Site and the remaining aluminum-clad spent nuclear fuel would be stored. The non-aluminum spent nuclear fuel would be accepted and placed in dry storage at INEL.

The Draft EIS was issued in April 1995. At this writing, the Final EIS is expected to be issued in February 1996 with a Record of Decision following at least 30 days thereafter. The Final EIS and Record of Decision will be based, in part, on the outcome of the Interim Management of Nuclear Materials Environmental Impact Statement discussed below.

Interim Management of Nuclear Materials at the Savannah River Site (9)

In early 1992, DOE announced an end to defense-related chemical separations activities of spent nuclear fuel to recover highly-enriched uranium. This decision was based on the end of the Cold War and a reduction in the demand for new materials for nuclear weapons. The cessation of processing operations resulted in a large inventory of nuclear materials being caught in various stages of the historic production cycle at SRS that require continued management. Some of the methods used to store these materials potentially pose risks to the environment or the safety and health of SRS workers or the public because, at the time DOE suspended the production cycle, many of these materials were either in a form or were stored in a manner that was intended for only temporary periods (i.e., one to two years). In some cases, the material's physical or chemical form poses a risk; in other cases, the material simply needs to be repackaged or moved to another location to ensure safe storage.

The Interim Management of Nuclear Materials Environmental Impact Statement (IMNM EIS) evaluates the environmental impacts that could occur from alternatives for the management of nuclear materials at SRS that would be initiated over the next ten years. Some of the nuclear material at the Savannah River Site may require near-term stabilization to ensure continued safe management. Materials that are candidates for stabilization are either in forms (e.g., liquid) that present inherent management risks or stored in facilities (e.g., reactor disassembly basins) that were not designed for long-term storage, or both. Stabilization would be achieved by chemical separation of high-risk production fuels, and other processing/conversion steps. The IMNM EIS also evaluated alternatives for the restart of facilities which could be used for chemical separation of the foreign research reactor spent nuclear fuel as well.

The IMNM EIS was issued in Draft in March 1995 and in Final in October 1995. The Final IMNM EIS identifies stabilization (i.e., processing/chemical separation) as the preferred alternative for the management of certain high-risk types of material. The IMNM Record of Decision, released in December 1995 (10), announces DOE's intention to begin operations to stabilize most of these high-risk materials, consolidate stable materials, and store all SRS materials onsite until the Department resolves issues regarding their future disposition. The Record of Decision also declares that upon completion of further analysis, DOE will issue a subsequent Record of Decision to announce the Department's final stabilization strategy for some of these at-risk materials (e.g., neptunium-237 and plutonium-239 solutions).

Further, the IMNM Record of Decision announces DOE's amended preferred alternative for the management of aluminum-clad, highly enriched uranium fuel from SRS reactors. Based upon further consideration and resolution of crucial management concerns such as cost, schedules, and technical uncertainties, DOE now considers the stabilization of these materials as the preferred management strategy. In particular, aluminum-clad (spent fuel) targets would be processed in preparation for vitrification in the Defense Waste Processing Facility. The Department will issue a subsequent Record of Decision on aluminum-clad materials in the near future.

LEGISLATIVE INITIATIVES

Fiscal Year 1996 Energy and Water Development Appropriations

The FY 1996 Energy and Water Development Appropriations (11) bill includes $400 million in total, including $85 million (to be held in reserve) towards the construction of an interim storage facility for spent fuel and $315 million for the Civilian Radioactive Waste program to, in part, continue studies at Yucca Mountain. The appropriations bill directs the Department to refocus the repository program to include interim storage development while completing the core scientific activities at Yucca Mountain. Activities include completing the excavation of the necessary portions of the exploratory tunnel and the scientific tests needed to assess the performance of the repository. Further, DOE is directed by Congress to defer preparation and filing of a license application for the repository with the Nuclear Regulatory Commission (NRC) until a later date. Instead, DOE's goal is to collect the scientific information needed to determine the suitability of the Yucca Mountain site and to complete a conceptual design for the repository and waste package for submission to NRC at an appropriate future date.

These directives significantly impact the schedule of repository program activities and, at the same time, add a new dimension to program planning, namely the prospect of a centralized interim storage facility. DOE will no longer work toward the preparation of a license application for the repository beginning in 1996 with expected submission to NRC in 2001 as previously scheduled. The potential availability of an interim storage facility could impact the DOE spent fuel program strategy in terms of the Department's current plans for new interim storage facilities. It is premature, however, for the DOE spent fuel program to consider the use of a centralized interim storage facility as a storage option for its own fuel when such a facility would be built primarily to store commercial spent fuel.

Legislative Initiatives to Amend the Nuclear Waste Policy Act

While the FY 1996 Energy and Water Development Appropriations bill directs $85 million towards the construction of an interim storage facility, the actual implementation of the directive is contingent upon the approval by Congress and the Administration of a separate measure directing DOE to build an interim storage facility. The most prominent legislation before Congress that seeks to reshape DOE's spent nuclear fuel management program are companion bills to amend the Nuclear Waste Policy Act of 1982. In February 1995, Representative Fred Upton of Michigan introduced H.R. 1020 (12), the Nuclear Waste Policy Act of 1995. In September 1995, Senator Larry Craig of Idaho introduced its counterpart, S. 1271 (13), before the Senate.

These measures would authorize DOE to construct and operate, in a phased approach, an interim storage facility for spent fuel at the Nevada Test Site. (It should be noted, however, that the Administration is opposed to the companion bills' language specifying this location for the interim storage facility until a 1998 viability assessment on whether or not Yucca Mountain is a suitable site for the geologic repository.) The Senate bill increases the maximum capacity of the facility from 40,000 metric tons authorized in the House legislation to 100,000 metric tons. Both bills would also require DOE to begin accepting commercial spent fuel and high-level radioactive waste no later than January 31, 1998. The bills provide for additional DOE-owned spent fuel and high-level waste to be stored once an annual acceptance rate from civilian power reactors has been achieved. This would include Naval spent fuel and DOE-owned spent fuel resulting from atomic energy defense activity and from foreign research reactors.

Legislative Initiatives to Amend the Waste Isolation Pilot Plant Land Withdrawal Act

Legislative initiatives to amend the Waste Isolation Pilot Plant (WIPP) Land Withdrawal Act would also impact the DOE spent fuel program since DOE spent fuel shipments to INEL are tied to transuranic waste shipments out of Idaho as specified in the Settlement Agreement with the State of Idaho. In particular, the Agreement would suspend any shipments of DOE spent fuel after April 30, 1999 to INEL unless shipments of transuranic waste from INEL to the Waste Isolation Pilot Plant (located in New Mexico) or another facility are proceeding at a specified rate.

There are two key legislative initiatives underway to amend the WIPP Land Withdrawal Act passed in 1992. These are H.R. 1663 (14) sponsored by Representative Joe Skeen, and S. 1402 (15) sponsored by Senator Larry Craig. These proposals seek to eliminate regulatory duplicity, and unnecessary budget expenditures and delays in arriving at a disposal decision. Both bills are very aggressive in attempting to reach a WIPP disposal decision.

Skeen's proposal provides that the intent of Congress is for DOE to reach a disposal decision no later than March 31, 1997. This is almost one full year ahead of the current WIPP Disposal Decision Plan schedule (the WIPP Disposal Decision Plan shows a decision by January 1998). However, Skeen proposes to reduce the Environmental Protection Agency's (EPA's) role from "regulator" to that of "advisor" by only commenting on, and not certifying by rule, the DOE application for compliance with the disposal regulations. DOE is insistent that the EPA role remain that of a regulator.

The Craig bill for the most part retains EPA's role as that of regulator by providing for EPA's certification of DOE's application for compliance

with disposal regulations. However, the Department is concerned with the limited review role that the EPA and the general public would have in the certification process. The Craig bill also calls for a firm target date for the opening of the WIPP facility by providing that the intent of Congress is that after the Administrator's review and certification, the Secretary will begin the disposal phase no later than June 30, 1997. DOE agrees with setting a date to begin disposal operations at WIPP as early as practicable within the constraints of the EPA review and certification schedule.

Legislation on External Regulation of DOE Nuclear Facilities

In January 1995, the Secretary of Energy formed the Advisory Committee on External Regulation of U.S. DOE Nuclear Safety in response to congressional interest in external regulation of DOE nuclear facilities. In its December 1995 (16) report, the Advisory Committee recommended ending DOE self-regulation and identified the pros and cons of using the Nuclear Regulatory Commission or an agency based on the Defense Nuclear Facilities Safety Board as the DOE's future regulator of nuclear facilities. Furthermore, the Committee's report outlined key principles for external regulation including enforcement approaches, public participation requirements, relationships with state regulators, and guidelines for reconciling external safety oversight with DOE's legitimate national security imperatives. The Committee's recommendations, if implemented, would substantially redefine the regulatory framework under which DOE must operate and would contribute to DOE and Congressional efforts in developing legislation for external regulation in the coming years.

SUMMARY

In 1995, the Department of Energy has made considerable strides in the Spent Nuclear Fuel Program with the establishment of a management strategy for the treatment, storage and ultimate disposition of the Department's anticipated 2,800 MTHM of DOE-owned spent nuclear fuel. This strategy is outlined in the Office of Spent Fuel Management's November, 1995 Interim Storage Plan and Program Plan. These documents include the establishment of clear time-lines for the assurance of safe existing conditions, achievement of safe existing conditions, and preparation for the ultimate disposal of spent fuel in a geologic repository.

Legal challenges to DOE activities, State and Federal government agreements concerning spent nuclear fuel, NEPA documentation and Records of Decision concerning DOE-owned spent fuel storage, processing, and ultimate disposition, and various legislative initiatives that affect the timing of repository availability, will all affect the direction of DOE's spent nuclear fuel program. This paper has attempted to introduce and examine several of these influences and provide insight concerning their impact upon the future of the Program.

Long-standing litigation with the State of Idaho concluded with a negotiated Agreement between DOE, Department of Navy and the State. These negotiations were undertaken due to paramount national security interests and were a necessary step in moving DOE's spent nuclear fuel program forward.

Current NEPA documentation for the program will lead to pending decisions affecting the State of South Carolina. Recently, the Interim Management of Nuclear Materials EIS Record of Decision announced DOE's intention to chemically separate certain high-risk materials at the Savannah River Site. One such decision pending in the near future is whether or not to

adopt a policy to manage foreign research reactor spent nuclear fuel in the United States. Such policy decisions may necessitate negotiations with South Carolina so that DOE can implement activities in a timely manner at the Savannah River Site. If necessary, negotiations would be predicated on overriding national security interests. As in the case of Idaho, such an agreement would be another example of redefining Federal-State relations to jointly implement policies at DOE management sites. It is expected that a new legislative framework will evolve that will help refine the path forward for the DOE spent nuclear fuel program, especially with regard to the timing/availability of a centralized interim storage site for civilian and DOE-owned spent nuclear fuel, a permanent geologic repository, and the Waste Isolation Pilot Plant. In addition, it is expected that Congress will act in developing legislation for external regulation of DOE nuclear facilities that will have implications to the DOE spent nuclear fuel program.

THE EXPERIENCE OF INDUSTRIAL REPROCESSING AT LA HAGUE

Ph. Pradel
P. Ledermann
COGEMA
2 rue Paul Dautier
78140 - Velizy Villacoublay
France

ABSTRACT
The full Reprocessing-Conditioning-Recycling (RCR) concept is an integral part of the French nuclear policy, initiated in the 1970s. COGEMA operates the World's largest reprocessing plant in La Hague, France with a 1600t/year reprocessing capacity. The plant serves the French utility and 27 electricity utilities from other countries. COGEMA has developed extremely sophisticated technologies over the past 30 years to treat the large quantities of fuel it reprocesses yearly and their diverse nature, both French and foreign.
Today, the La Hague plant has achieved a 99.88% recovery of the fissile materials contained in spent fuel and has developed safe waste conditioning through vitrification, a technology internationally recognized as the best for high level waste. In spite of its proven mastery of reprocessing on an industrial scale, COGEMA continues to apply the ALARA principle. Thus, new technologies for waste minimization are being developed, including, from now to the year 2000, the suppression of bitumen packaging, the compaction of hulls and end-pieces, and the reduction of technological waste originated in the reprocessing operations.
Decreasing the plant's environmental impact and the personnel's occupational exposure have also been major goals ever since the plant was conceived. The environmental impact is negligible. The surrounding air, land, and sea are systematically monitored. Both sample analyses and continuous measurement instruments demonstrate the extremely low level of radioactivity added to the natural level. Similarly, in applying the ALARA principle, radiation safety is a major concern, and has shown very effective. The average dose in 1995 was 0.20 mSv/man/year, and has decreased to less than 10% of the dose equivalent resulting from natural radioactivity.
The plant's design has made it possible to improve the effluent management, the waste segregation procedures, the vitrification units, crane equipment, etc... without disturbing production. Thanks to the permanent improvement of the facilities, the total volume of waste produced is now less than what it would be in the direct disposal of spent fuel option. In contributing to an optimal use of natural resources through recycling and reducing both the toxicity and the volume of its waste, COGEMA has demonstrated its commitment in favor of sustainable development.
INTRODUCTION
France opted in the 1970s to close its nuclear fuel cycle, thereby optimizing the industrial use of fissile materials and minimizing waste production. The enactment of this policy led to the construction of the World's largest reprocessing facility at La Hague in 1980s. With the start-up of UP3 in 1990 and of UP2-800 in 1994, the Reprocessing-Conditioning-Recycling concept has been completed, both as a part of the French electricity program and as an industrial service facility for foreign customers.
As the La Hague plant's operator, COGEMA has demonstrated its capacity to master large-scale reprocessing technologies. It has also led the way in the improvement of quality, safety, and waste minimization. The operational experience of the plant shows that production, maintenance and a low environmental impact are fully compatible, thanks to a carefully planned design and strict operational procedures.
NEARLY 30 YEARS OF EXPERIENCE

The Hague's total reprocessing capacity of 1600 metric tons per year has been achieved through constant improvements over three decades. The industrial mastery of reprocessing and recycling is evidenced by the progress made in attaining the full capacity : it took ten years to reach the nominal throughput for UP2-400, only five to reach double that throughput at UP3, and hardly over one year for UP2-800, commissioned in 1994, to reach its nominal capacity.

Quantitative and Qualitative Experience

To date, over 17,000 metric tons of spent fuel have been transported from European and Japanese reactors to La Hague, with over 4200 shipments by rail or sea. Every year, the French utility (EDF) sends approximately 1000 tons to the site. Figure 1 shows the combined UP2 and UP3 facilities have reprocessed 8262 tons of spent fuel as of January 1, 1996.

Fig. 1

La Hague also bases its experience on a wide variety of fuel inputs. Over the years, these fuels have included fuels from Light Water reactors (both PWR and BWR) as well as the tail end of the GCR reprocessing. Feasibility of reprocessing MOX fuel was demonstrated by a successful campaign in 1992. Lastly, fuel from the first French fast breeder reactor was reprocessed at UP2 as well. The diversity lies not only in the nature of the fuels but in the burn-up as well, spanning from 10 000 to 45000 Mwd/t. Thus, COGEMA's operational experience is both broad and deep. Through this experience, a 99.88% recovery rate has been achieved for recyclable materials (uranium and plutonium).The remainder (0.12%) is vitrified along with the fission products, which represent 99% of the radioactivity contained in the spent fuel, but only 3% of its mass.

Advanced Technology

The vitrification technology was developed in France. It was implemented in the AVM facility at Marcoule, and later on, in the R7 and T7 facilities at La Hague. It is based on a two-step process, which separates the calcination and glass melting operations. The final product, vitrified residues, are today the only HLW form licensed by the French and foreign regulatory bodies. Its confinement qualities are based on a 15 year qualification program performed at CEA (the French public research institution for atomic energy), and on the active quality control and quality assurance programs set forth by the operators of the vitrification facilities.

WASTE MINIMIZATION

Above and beyond the high degree of recovery, COGEMA is concentrating its efforts on three waste minimization programs : the suppression of bitumen packaging, the compaction of hulls and end-pieces, and the reduction of "technological waste".

Suppression of Bituminized Packages

Until now, medium and low-level effluents were routed to the waste treatment facility "STE3" and treated by a "coprecipitation process" involving coprecipitation by different additives, decantation and filtration steps, which provides for an efficient decontamination factor. The active sludges were conditioned in bitumen and considered as Intermediate Level Waste. These wastes exhibit an alpha activity above the threshold of 3.7 GBq/t (0.1 Ci/t) and are not acceptable by a surface disposal site in France. The quality of the bitumen waste form, necessary for underground storage, has been demonstrated after a comprehensive characterization program performed by the CEA and acknowledged by the French Safety Authorities and most foreign governmental authorities.

However, the bitumen matrix is no longer necessary. Feedback from the operation of the UP3 plant shows that the volume and the activity of low and intermediate level effluents was, from the beginning, significantly lower than estimated at the design stage. This comes from the very high performances of the extraction cycles, resulting in lower than expected activity levels of some of the effluents and allowing for significant improvements in liquid waste management.

The improvements are based on both a more sophisticated segregation of the wastes according to their chemical and activity content, and the implementation of additional evaporation capacities in the plant. Effluent segregation allows for the discharge of the very low active streams to the sea whenever possible, after filtration and monitoring, without increasing the released activity.

Effluents from the analytical laboratory also need to be considered. These effluents traditionally include a mix of sample excess and chemical reagents which are not present in the main process. Moreover, the analytical effluents contain different levels of alpha and beta-gamma activity. The improvement of their management first relies upon a segregation within the analytical lines. According to their nature, they will be either recycled into the plutonium purification cycles (alpha bearing effluents) or routed to the vitrification unit (beta-gamma effluents) whenever possible. For effluents containing unwanted chemicals, a special coprecipitation unit will be used to separate the alpha activity. The amount of unwanted ions such as phosphates, sulphates, and chlorides is being significantly reduced through the use of alternative analytical methods.

As of mid-1995, these improvements make it possible to route practically all the concentrated activity to the existing vitrification facilities. Thus, the need for coprecipitation and bituminization treatments has disappeared in normal operating conditions for the intermediate and low level effluents from the UP3 and UP2-800 plants. The resulting small increment of activity conditioned in the glass will not increase the volume of glass produced.

Compaction of Hulls and End-pieces

Hulls and end-pieces separated from the irradiated fuel in the head-end of the reprocessing plant are currently conditioned by cementation, a process which was licensed by the French regulators, while COGEMA continued investigating alternative possibilities. COGEMA is currently developing a compaction technology which should be operational before the end of the decade. Compacted pellets will then be loaded in a glass-type canister, and the corresponding volumes should decrease to approximately 0.15 m3/t of Rep U.

Reduction of "Technological Waste"

The last category of waste conditioned at the reprocessing plant originates not from the fuel itself, but from the reprocessing operations, and is called "technological waste". All the technological wastes are now conditioned in a single type of fiber-concrete container. A drastic minimization has already been obtained by comparison to the design waste volumes, by relying on the high equipment reliability and improved sorting, performed at the entrance of the solid waste processing facility (AD2). The sorting makes it possible to send more than 80% of the technological waste to surface disposal. Further minimization could involve a compaction, incineration and a plutonium decontamination

process based on oxidizing dissolution, as well as the implementation of new repairing techniques.
The volumes of each waste category are summed-up in Fig. 2, where are compared the design values and those derived from the actual plant operation. The figure shows that the amounts of waste produced are quite a bit lower than expected. From the beginning of the oxyde fuel reprocessing at UP3, great steps have been taken toward minimizing the different types of wastes resulting from the process. At this stage, the overall volume of long-lived waste (under 1.0 m3/t) is already lower than the volume of waste which would result from a direct disposal of the irradiated fuel in a once-through option (2m3/t). This achievement is due to innovative technologies and effective management of waste conditioning.
Fig. 2
Expected Results
After the completion of all the necessary developments, the overall volume of high level and long-lived waste will be under 0.5 m3/t of Rep U. Most of the waste will be delivered in standard, glass-type canisters. Low-level technological waste will be conditioned in standardized fiber-concrete containers, in order to facilitate handling and optimize storage.
LOW ENVIRONMENTAL IMPACT AND OCCUPATIONAL EXPOSURE
Both the plant's design and its operation are aimed at making the environmental impact negligible. Authorized limits of alpha and beta activities have been determined for the site's liquid releases, based on an environmental impact assessment. As seen in Fig. 3 the actual discharges have been continuously decreasing and are well below the authorized levels, despite the increasing quantities of fuel reprocessed yearly.
Fig. 3
A direct measurement of the site's environmental impact is provided by the Health Physics Department. Its systematic monitoring of the surrounding air, land and sea on the basis of both sample analyses and continuous measurement instruments shows the exceptionally low level of added radioactivity. A particular attention is paid to the presence of radioelements in dairy products and seafood. The results show that there is a continuous decrease of activity in these products down to less than 10% of the natural radioactivity level.
Reducing the occupational doses to COGEMA and subcontractor staff is a unending quest when one applies the ALARA principle. The level achieved shows that radiation safety procedures have been truly effective. In 1995, the average value of 0.20 mSv/year/man was reached, which is less than 1% of the value authorized by current regulations. Figure 4 shows the decreasing trend in occupational doses over the last 10 years.
Fig. 4
EFFICIENT IMPLEMENTATION OF MODIFICATIONS
It should be noted that it has been possible to introduce the improvements described above without interrupting the production process because the initial design accounted for further modifications.
The increased sophistication of the waste segregation, and the addition of several evaporation units have required substantial modifications in the existing facilities. The lay-out concept of UP3, where active units are located in specific cells, has made it possible to perform these modifications without significant interferences in the process, while

minimizing the dose rate to the workers. The connections to the operating active units have been facilitated by the waiting pipes provided outside active cells.
Other modifications have been achieved in vitrification units, with positive consequences for waste minimization. From the start-up of R7 and T7, uninterrupted progress has been achieved without disturbing production, in particular :

- implementation of a new melting equipment to increase the melter lifetime up to 3000 hours ;
- addition of a gas containment system to decrease the pouring cell contamination;
- modifications of a crane equipment and its maintenance procedures to improve reliability.

CONCLUSION

The Environmental Summit held at Rio in 1992 ended with the commitment of industrial countries in favor of sustainable development. For years, France's reliance on nuclear energy, which led to drastic reductions of toxic emissions even before the Rio decisions, has been a confirmation of such a commitment. The early choice of a closed fuel cycle is the logical continuation of its nuclear policy, and is fully consistent with the principles contained in the Rio decisions. Spent fuel reprocessing significantly contributes to:

- environmental protection : waste is safely conditioned in a form appropriate to its nature;
- conservation of natural resources : recycling of energetic materials allows the recovery of nearly 20,000 TOE per metric ton of spent fuel.

The fact that the reprocessing and recycling facilities are operated in a way which minimizes the amount of liquid and solid waste produced is also consistent with sustainable development. This has been COGEMA's unvarying strategy, exemplified by the commissioning of modern plants at La Hague, UP3 in 1990 and UP2-800 in 1994. COGEMA is completing a first important step with the suppression of bituminized waste in modern facilities, and new developments are being launched, which will bring a further minimization of high level and long lived-waste.
The total volume of high level and transuranic waste produced in UP3 is already less than what would result from direct disposal of irradiated fuel. From now on, all but an infinitesimal amount of the activity will be concentrated in glass. All the necessary modifications are performed without disturbing plant production, because their possibility is accounted for in the initial design. By this continuous improvement strategy with regard to quantity as well as quality of wastes produced, COGEMA has demonstrated its commitment in favor of sustainable development.

10-3

STATUS OF THE NEW FRENCH MOX FABRICATION PLANT: MELOX

Willy Fournier
MELOX
Les Tourettes - CD 138
30203 - Bagnols sur Ceze
France

ABSTRACT

The MELOX plant, which is currently entering industrial operation, is an important element of the RCR strategy (Reprocessing, Conditioning and Recycling) which is steadily implemented in France. Being the first high throughput MOX fuel manufacturing facility, MELOX plant can be seen as an outstanding achievement, based on well-tried techniques, but introducing several innovative features in terms of radiation protection as well as environmental concern.

While the first decision was taken in 1985, construction started in 1990 and active operation approval was granted by Regulatory Authorities in August 1994.

Industrial start-up is currently underway, and production is progressively increasing, implying customer's involvement in a detailed and complete qualification of the whole process.

Acquired results give confidence that the objectives of full-scale plutonium recycling will be met, serving French and foreign utilities' optimized back-end strategies. As a result, further capacity and flexibility extensions are envisioned.

THE MELOX CONTEXT

From the very origin of the French nuclear program, reprocessing of spent fuel and recycling of valuable materials such as uranium and plutonium has been the thorough and coherent French strategy. Today, the possibility for the use of plutonium into MOX fuel appears economically sound, and that is why EDF decided in 1985 to recycle plutonium in some of its PWR 900 MW units. This strategy implements a set of well-mastered industrial operations, and at three places, the same flow of recycled materials is to be achieved : at the output of the reprocessing plants, at the input of the fuel manufacturing facilities and at the input of the recycling-dedicated reactors.In order to cope with EDF planned requirements (recycling in 20 to 28 PWR reactors), and to serve foreign utilities as well, a consistent industrial organization was established through industrial and commercial agreements among EDF, FRAMATOME and COGEMA on the one hand, and between COGEMA and BELGONUCLEAIRE (BN), on the other hand.

It appeared that existing facilities (BN P0 plant at Dessel and COGEMA Cadarache plant) would only partly match the projected needs and that additional capacity would be necessary. As soon as 1985, preliminary studies were undertaken for the construction of a large-scale MOX plant, MELOX, the design capacity of which is 120 tons of Heavy Metal per year (tHM/y).

The MELOX plant is located on the site of Marcoule, on a separate 50000 m2 area, and includes all manufacturing operations from UO2 and PuO2 powders reception to assembly delivery. It comprises two main buildings : a manufacturing building with production lines and laboratories and a scrap and waste treatment building including an incinerator for burnable waste.

The MELOX Company, created by COGEMA and FRAMATOME in order to supervise the construction of the plant and operate it, is now proceeding with industrial start-up activities aimed at a full qualification of the entire plant resulting in a progressively increasing production during the next months. After describing some of its specific design features, this paper gives information about some milestones and current achievements (as of mid-January 1996) of the MELOX plant industrial operation.

MELOX SPECIFICITIES

MELOX is the first high-throughput MOX fuel manufacturing facility to be put into operation in the world. While taking full benefit from the excellent performance of previous generation plants, MELOX is designed to fulfill the foreseeable requirement trends in both fuel management and modern safety and environment concerns.

An Innovative Plant Based on Well-tried Techniques

Relying on the outstanding experience of the pre-existing facilities (MOX fuel at Dessel and Cadarache and UO2 fuel at Dessel, Romans and Pierrelatte), MELOX is implementing, whenever possible, proven and qualified industrial-scale processes and techniques.

The reference process is the well-mastered MIMAS process (Micronized MASter blend) which has been successfully implemented in the Dessel plant since 1984. The PuO2 powder is micronized with a part of the UO2 powder to form a primary blend of 30% plutonium content, which is then mechanically diluted and mixed with a free-flowing UO2 powder to obtain the specified content of the MOX fuel. Sintering is then performed under temperature and gas blanket conditions adjusted to the densification and diffusion requirements for the pellets.

Research and development activities have been performed in order to confirm the choice of some equipment, devoted to homogenizing, multi-punch pressing, pellets grinding, rod welding and rod repairing. Moreover, some innovative equipment have been introduced, such as automated sorting of pellets for surface defects and rod decontamination before assembling.

A Modern Unit Coping with Future Trends

Although dedicated to a number of FRAMATOME assembly designs, MELOX offers to the utilities a flexible use of MOX fuel. As a result, it may receive and handle a wide range of basic nuclear materials. This implies the capability of using high-burnup and aged plutonium, which has consequences, through Pu238 and americium content, both on the specific thermal energy to be evacuated and on radiation shielding to be installed. On the other hand, the trend towards an increased MOX fuel discharge burnup leads to high plutonium content in the fabricated fuel.

MELOX characteristics are given below :

- Pu 240/Pu total 17 %
- Pu total/U+Pu+Am 12.5 %
- Am 241/Pu+Am 30 000 ppm
- average thermal power 17.6 W/kg PuO2

Safety and Environmental Concerns

A special design effort, while coping with the above requirements, has been devoted to set the annual dose of most factory operators to a value below 5 mSv/yr, which is one tenth of the current regulatory limit. This implies almost total automation of production and required extensive optimization studies tailored to each workstation.

Another design effort has been devoted to waste minimization. Besides the recycling of most of the scraps in the process line, the objective is to achieve chemical treatment of unsuitable scraps, to decontaminate metallic waste before conditioning and to incinerate organic waste with chemical treatment of the ashes. A significant decrease of residual plutonium in the waste should be achieved (the expected order of magnitude is about 500 g/yr in the final waste).

On the other hand, low activity liquid waste will be treated in the COGEMA Marcoule treatment unit. Radioactive discharge from MELOX will

represent one thousandth of the overall limit authorized for the Marcoule site.

The MELOX plant can be seen as an outstanding achievement, taking full benefit from previous experience, while introducing several innovative features in terms of radiation protection as well as environmental concern. It is a major input in the national energy policy, as an important element of the plutonium recycling strategy.

SOME MILESTONES

Governmental Authorities licensed the MELOX plant as a Basic Nuclear Facility in May 1990. Construction started in 1990 and civil works of the production building were completed in 1991. After main equipment installation, inactive testing program started in 1993.

Several stages have been progressively performed and, as they proceeded, increasing confidence has been gained concerning satisfactory operation of the whole production line as well as of all its parts.

A safety advisory commission meeting held in March 1994 led to active operation approval by Regulatory Authorities in August 1994.

A step-by-step strategy has been implemented for the commissioning procedure. The objective is to provide the customers (i.e. the fuel vendor, FRAGEMA, a FRAMATOME/COGEMA joint venture, and the final user, EDF) with a gradual, but complete, demonstration that the fabricated products are of required quality. The result is the "process qualification", granted by the customers, which ensures that the product quality will reliably meet his requirements.

As a general rule, back stream units are to be qualified when qualifying one unit. Thus, the assembly unit was commissioned first, using rods coming from the Cadarache plant : as soon as December 1994, authorization was granted by FRAGEMA and EDF to proceed with industrial assemblies production. Then, powder-pellet and rod units can be qualified using the normal process pathway.

For the powder-pellet unit, parametric tests have been performed using exclusively UO2 powders, in order to minimize scrap production during start-up. After the special authorization received in February 1995, the first welded cartridge box containing plutonium was opened on February 7th, allowing operation of the powder-pellet workstations.

A verification phase for the parametral tests was necessary and was performed using little quantities of PuO2 in the laboratory test-lines, sintering being performed in the normal line furnace. The acquired results, involving high and low plutonium contents, were satisfactory and allowed UO2 tests validation.

Full industrial operation of the MOX fabrication line was evidenced, as the first MELOX rods were delivered in July, 1995.

MELOX start-up is being performed according to a very carefully prepared logical course and implemented using a step-by-step program, implying customer's involvement in a detailed and complete qualification of the whole process. Full capacity will be reached progressively by increasing the capacity of each individual piece of equipment. Acquired experience gives confidence that this will be achieved without major difficulty, thus demonstrating the validity of the original options.

PRESENT STATUS AND ACQUIRED RESULTS

Assembly Unit

This unit is fully qualified and is functioning on-line with the actual production of 76 assemblies in 1995, 40 of which have been delivered to the nuclear power plants and loaded in the reactor core. It should be

noted that, at the same time, dispatching and transport activities have been fully qualified as well.

Rod Unit

The first MELOX rods were produced in July. More than 800 rods have been manufactured in 1995. They are a part of the first campaign, launched in order to produce a whole reload (16 assemblies with three plutonium contents).

Powder and Pellet Unit

An industrial demonstration stage is currently in progress, using representative quantities of plutonium (hundreds of kg). This stage involves the whole line. At the end of the year 1995, 9 tHM of Mixed Oxide have been processed, of which about 5 tHM have undergone pelletizing.

Two lines of pelletizing and two furnaces are being, by now, operated with PuO_2.

Waste Conditioning and Incineration Building

This building was officially transferred from the engineering team to the operator in April, 1995. Inactive tests for the incinerator are still in progress and the results are to be submitted to the Safety advisory commission. On the other hand, the waste conditioning and storage part of the building has been granted active operation authorization and has started dealing with wastes coming from the fabrication building.

It should be noted that, as far as no fabrication is involved, customer's qualification is not required in this building.

CONCLUSION

Through a consistent and large-scale program, recycling of plutonium in light water reactors is a mastered and industrial reality. It implements a set of effective operations, the impact on the environment and human health being set well below required limits.

COGEMA effectively possesses a fully coherent facility system for nuclear fuel back-end optimization with MELOX, the Cadarache plant and the reprocessing facilities in La Hague. The maturity of the RCR (Reprocessing, Conditioning and Recycling) strategy in France is being reached.

While the full-scale operation of this strategy will be reached in France before year 2000, COGEMA is able to serve foreign, European and Asian utilities as well. As far as the MOX manufacturing step is concerned, COGEMA considers the possibility of increasing its capacities in order to serve customers who want their MOX fuel to be fabricated in France.

When providing a three-shift operation on some units, MELOX capacity can easily reach a 160 tHM/yr production for standard fuels, which is planned by year 2000. Besides, COGEMA is studying an extension project : adding a fourth sintering furnace and a related independent line could further increase the capacity by 50 tHM/yr with enhanced flexibility concerning BWR MOX fuel fabrication.

COGEMA will adapt to the actual demand and has the references, the experience and the technology to demonstrate the feasibility of a fast, safe and reliable program of MOX recycling in LWRs. While successfully applied to the civilian nuclear industry, such a satisfactory experience could be brought to solve the current concern about weapons plutonium inventory disposition : "moxification of this military plutonium would product electricity while burning it and deteriorating its weapons value.

"THE INEL APPROACH"
ENVIRONMENTAL RESTORATION PROGRAM MANAGEMENT AND IMPLEMENTATION METHODOLOGY

Kathleen Falconer
Lockheed Martin Idaho Technologies
Lisa A. Green
U.S. Department of Energy

ABSTRACT

The overall objectives of the INEL Environmental Restoration (ER) Program management approach are to facilitate meeting mission needs through the successful implementation of a sound, and effective project management philosophy. This paper outlines the steps taken to develop the ER program, and explains further the implementing tools and processes used to achieve what can be viewed as fundamental to a successful program. The various examples provided will demonstrate how the strategies for implementing these operating philosophies are actually present and at work throughout the program, in spite of budget drills and organizational changes within DOE and the implementing contractor.

A few of the challenges and successes of the INEL Environmental Restoration Program have included: a) completion of all enforceable milestones to date, b) acceleration of enforceable milestones, c) managing funds to reduce uncosted obligations at year end by utilizing greater than 99% of FY-95 budget, d) an exemplary safety record, e) developing a strategy for partial Delisting of the INEL by the year 2000, f) actively dealing with Natural Resource Damages Assessment issues, g) the achievement of significant project cost reductions, h) and implementation of a partnering charter and application of front end quality principles.

BACKGROUND

The Idaho National Engineering Laboratory (INEL) was established in 1949 by the U. S. Atomic Energy Commission to build, operate, and test various nuclear reactors and fuel processing plants, and to provide and operate various related support facilities. Since that time, 52 reactors have been constructed, 13 of which are still operable. Today, the INEL also supports other government-sponsored projects including energy, defense, environmental, and ecological research.

The INEL is located 42 miles west of Idaho Falls, Idaho and occupies 890 square milers of the northwestern portion of the Eastern Snake River Plain. The INEL is bound on the northwest by three mountain ranges: Lost River, Lemhi, and Bitterroot. The remainder of the INEL is bound by the Eastern Snake River Plain.

The Environmental Restoration (ER) Program was established in 1989, when the INEL was placed on the National Priorities List. Ten waste area groups (WAGs) were created based on geographical boundaries for management of remediation activities. Contamination the ER Program deals with includes radioactive and mixed waste in soils, groundwater and that buried at disposal facilities.

During the first operational years of the ER Program, it became apparent that careful project management would be essential for the milestones negotiated in the Federal Facilities Agreement and Consent Order (FFA/CO) to be met. The approach described here was not conceived on the first day of operations of the program, but rather is the result of several years of evolution that included the pains of learning, as well as the

excitement of success. This approach has helped the INEL ER Program in meeting or beating the enforceable milestones in the FFA/CO.

Environmental restoration programs at other sites can benefit from the INEL ER Program's years of continual learning and improving, by reviewing the approach used at the INEL and incorporating those activities that improve their program. Modeling new processes based on the experience at the INEL will result in reduced schedule durations and related costs for environmental restoration.

AN INTRODUCTION TO THE APPROACH

The Need for Improved Program Management

The overall objective of the INEL ER Program management approach is to facilitate meeting mission needs. This is accomplished through the successful implementation of a sound and effective project management philosophy.

The INEL ER Program management approach assures the application of sound management principles to provide a disciplined, systematic, and coordinated approach to project management. This results in efficient planning, organization, coordination, budgeting, management, review, and control to achieve INEL ER objectives.

Employing a "value added" approach to guidance implementation ensures that DOE Environmental Management (EM) goals, strategies, and budgets are in alignment. Voids in EM guidance are jointly interpreted by DOE-ID led contractor task teams, and modified as necessary to suit INEL ER Program needs and requirements.

The INEL approach can be best described as systemic. Utilizing the focused principles of teamwork, communication, and consensus building provides the program with unity; thereby, enabling it to function as a fully coordinated, cohesive, and mutually supportive organization.

The INEL ER Baseline represents the successful integration of the program's cost, schedule, and technical work scope. It is from this level that all program elements are established and maintained. From the baseline standpoint, the process of maintaining a balance between the functioning elements of the ER Program (cost, schedule, and technical), and EM goals and priorities are established.

What follows provides some background on how we have developed our program, and focuses on the fundamental elements of our management methodology; describing the operating philosophies and the strategies for implementation.

Share Sound Management Philosophies

There is a strong desire by many organizations to learn how to do things more efficiently, to learn techniques that have substance, to learn useable processes that provide tangible results. They want to learn methods that will help them solve chronic, underlying problems and that focus on principles that bring long-term results. Something beyond typical management basics is needed.

INEL ER experience has proven the benefits of increased understanding through the sharing of information. Through this introduction to the INEL approach, there will be a sharing of ER program background and experience, and opportunities to demonstrate how to use the operating philosophies and strategies associated with their application. How these implementing strategies and operating philosophies can be adapted to suit many circumstances will also be demonstrated.

Through the collective experience of its participants, the INEL ER program has come to possess the tools, and lessons learned, and so on,

that has enabled the development of quick, economical, and environmentally sound processes that work, and that can be shared with others. There is also recognition that good communication and feedback are a key element in the continuous improvement process. The interaction and discussion that takes place in sharing information with others is an invaluable means of renewing and validating our operating philosophies. Through sharing of background and experience, the learning curve can be lessened for others, providing something that will save time and money, and ultimately increase functional effectiveness.

Stepping back, we have identified what elements have been present in each of the implementation steps taken in development of the ER program. The result of this retrospective examination is a list of operating philosophies which when properly applied, along with the implementing tools and processes described in this paper, have allowed ER to build a successful program.

INEL Operating Philosophies

Goal oriented approach (this is the key element and is also the first step)

- Clearly defined objectives
- Flexible assumptions
- Finite scope
- Value added concepts
- Cost effective, efficient

Teamwork (partnering)

- Communication
- Consensus building
- Contractor integration
- Unity of cause and purpose

Process oriented

- Systematic
- Coordinated approach
- Work to fill voids in guidance requirements
- Develop processes which are complimentary to existing (successful) processes

Incremental development

- Recognize this is an evolutionary process
- Improve process continuously
- Incorporate flexibility to suit program dynamics

Disciplined approach (commitment)

- Compliance with established processes
- Consistency
- Integrity/quality
- Credibility

Why These Philosophies Work

A sound management methodology, and a strategy to implement that methodology, is essential to ensuring that program management is reliable, well organized, consistent, and successful. A successful program embodies the successful integration of these operating philosophies along with the program's cost, schedule, and technical work scope. Using this approach, all program elements can be established and maintained from a central point of control. From that standpoint, the process of maintaining a balance between the functional elements (cost, schedule, and technical) and program goals and priorities can be easily achieved.

These operating philosophies stimulate a willingness and the capability to deal with exceptions encountered in building and using the various systems and processes, accepting that there are known incongruencies, but not allowing those incongruencies to distract from maintaining discipline with other systems/processes.

The following demonstrates how ER deals with the many influences on our program through the use of the operating philosophies, along with examples of the processes and tools developed to accomplish this. This in turn will help define the goals which make up "What is ER Program." Also included is a description of how the implementing strategies and operating philosophies can be established, or rather instilled within the various existing processes. The approach is a flexible application, and can be applied to a finite program or "fuzzy" program.

INEL OPERATING PHILOSOPHIES

The First Approach: Goal Oriented

The primary step is to be goal oriented. You must have established goals and a strategy to know where you want to go. You will need to develop a finite scope, define knowns, deal with unknowns as changes, and utilize assumptions. All actions taken need to be "value added" actions. Considering the many requirements placed on us from outside, it is important to use what is useful, modify it when necessary, but don't produce just to produce or to fill a square.

When the Federal Facilities Agreement was negotiated, the project managers from each of the stakeholders wanted the quickest and smartest cleanup possible. The negotiating team made of personnel from the U.S. Department of Energy, U.S. Environmental Protection Agency, and the State Environmental Agencies had a common goal. This goal was to ensure that releases or threatened releases were thoroughly investigated in accordance with the National Contingency Plan and that appropriate response actions were undertaken and completed as necessary to protect human health and the environment. Because the agreement is representative of the common goals of the team, the CERCLA process works quickly with regulators and performers communicating and moving forward.

Flexibility

This approach encourages timely remedy selection, flexibility for remedial action, and contingencies to respond to new information discovered during investigations. Through flexibility, implementing strategies and operating philosophies can be adapted to suit many circumstances. Flexibility allows all of the other approaches to work. Flexibility means to be willing to deal with exceptions, and building systems to accept exceptions as if they are inevitable. However, this should not distract from maintaining discipline with systems or processes; if the exception becomes the rule, it may be time to change the system or process.

Defining the technical scope and schedule for remedial action involves the approval of various outside agencies. ER Program management has the administrative flexibility to deal with external regulatory authorities in a timely and responsive manner. Flexibility encourages timely, outcome oriented remedy selection for remedial actions, and an ability to respond to new information discovered during investigations.

Teamwork

The process of identifying who is on the team is critical to your success. Teams should include regulators, government representatives, and

performing organizations as the principle team participants in the development of the scope of work.

It has been our experience that facilitated retreats have assisted in bridging the adversarial attitudes that existed at the beginning of the program. Communication is much easier if the participants can place a face with the name of a regulator.

Facilitated retreats have been used as a tool to develop better communication skills and to exchange information among participants in the decision process. A given benefit is that the parties to establish communication face-to-face in an atmosphere of neutrality; they are no longer talking to a stranger over the phone. This communication also allows members to establish a collective understanding of the program and its long range goals. Participants in the retreats have also been able to jointly define success in the completion of the project.

The generation of the formal ER Partnership Charter is the result of an off-site retreat conducted for all ER Program Waste Area Group Managers and Project Managers. The retreat was successful in developing a greater understanding of the shared values and responsibilities that must exist between DOE-ID and Lockheed Idaho Technologies Company, in order to fulfill the Program's goals.

The elements of the Charter are founded in the development and use of sound communication skills, and the use of same to facilitate completion or achievement of the ER Program goals. We are continually investigating effective ways to further develop and enhance the communication and facilitation skills of all ER Program participants, in order to maximize the progress made in implementing our Charter to date.

Process Oriented

The ER Program has developed strong hierarchy of processes or strategies which allow us to build the ER Baseline and to maintain it. This hierarchy of processes is auditable and consistent (back to the baseline). Each respective process is interrelated and complimentary of the others. Maintaining a "value added" management approach, each process has a specific fit and function. The result is an increased capability to respond to the natural dynamics of the program.

The Federal Facilities Agreement establishes a procedural framework and schedule for developing, prioritizing, implementing, and monitoring appropriate response actions in accordance with CERCLA, RCRA, and Idaho Hazardous Water Waste Management Act.

Preliminary Scoping Guidance documents were developed to facilitate implementation of the specialized sections of the facility agreement. All parties (contractors, DOE, and Regulators) agree to use the appropriate approach and assumptions to evaluate sites and minimize costly sampling and analysis plans and reduce RI/FS requirements. The success of these rapid decision processes has allowed completion of all enforceable milestones on orahead of schedule and on or under budget. ER has also been able to close over half of the sites in just under three years.

Successful Program Management and Implementation Processes

The INEL has focused on the development of a single integrated baseline which can respond to all DOE program and project management control requirements. The INEL ER Program Baseline represents the successful integration of the programs cost, schedule, and technical work scope. Numerous processes or mechanisms have been developed in order to organize the various elements of the ER program into a whole. All program elements are established and maintained at this level. These "baseline tools"

regulate the scope, schedule, and budget for the ER Program, and provide the means for the program to more efficiently address issue and concerns, and to support the requirements and interests of DOE-HQ, regulatory agencies, and various other ER stakeholders.

Hierarchy of Baseline Development Processes

The ER Program has developed a strong hierarchy of processes or baseline tools which allow us to build the ER Baseline and to maintain it. This hierarchy of processes is auditable and consistent (back to the baseline). Each respective process is interrelated, and complimentary of the others. A "value added" management approach is maintained, and each process has a specific fit and function. An increased capability to respond to the natural dynamics of the program is the result.

Life Cycle Planning (LCP) ProcessReplaces annual rebaselining efforts by allowing updating and refining of the baseline only when changes to the program requirements, assumptions, or resource availability are required.

INEL ER Code of AccountsLinks a uniform cost estimating process with accounting system(s) to facilitate cost capture (prior to COA being used, Cost Estimate Basis Sheets are used to document cost basis).

INEL ER Unit Price BookMaximizes the use of historical data and site experience through a unit price guide. The cost estimating focus group concentrates efforts to establish credibility, consistency, duration, and so on, relative to cost estimating system management for the INEL ER Program.

Project Risk/Contingency AnalysisDevelops contingency for the cost baseline to account for uncertainties, risk, and potential growth in scope that may result from unforeseen and unpredictable conditions. This process, which may be iterative, is performed by the Project Manager/CAM level down to the work package/task level, and ultimately establishes the cost baseline for the Control Account.

- Task levels are based on "level of confidence" in scope of worknot dollars
- Applied and controlled at the program level

Configuration Control/Baseline Management

- Uniform application of change control philosophy
- Uniform hierarchy for change control
- Change control scope oriented baseline elementone baseline
- Increase in programmatic understanding re:definition of Work Scope, integrated baseline reconciliation (periodic/all participants)
- Expedite submittal process through increased use of "redlines"
- DOE-ID ownership of all changes and DOE-ID concurrence required to "sponsor" Level 2 changes
- Uniform baseline reports
- Tie traceability back to funding
- Improved BCP process
- Increase quality of Baseline documentation.

Uniform Milestone Guidance/Scheduling ProcessUtilizes pre-negotiated milestone criteria that was determined through discussions with DOE-HQ, EPA, State, DOE-ID, Stakeholders, etc. Specific milestone coding, structure, and nomenclature with standardized milestone configuration management and controls. Utilizes standard logic.

Incremental Development

The first step for ER was to recognize that implementation of the program required an evolutionary process, incorporating flexibility, teamwork,

and continuous self-evaluation to suit program dynamics. This incremental development applies to both technical development and program management. Problems and issues are viewed from a global standpoint, relative to their effect on the program as a whole, and resolved as they appear on the horizonat the lowest level manageable. As the program has evolved, we have applied this approach by creating technical work teams for global issues affecting our program (for example, guidance document development, ATSDR, Cumulative Risk Assessment, BSAF, Eco Risk, Land Use, and so on). In addition, a Program Management Systems Development Initiatives (PMSDI) Committee was created to evaluate and make recommendations for program management improvements. These teams or committees are made up of personnel from each of the affected organizations, and are asked to make recommendations for the program by taking incremental development steps to achieve our end goals.

This collective energy can give an issue the broad analysis necessary to resolve complex problems. Issues are resolved at the appropriate level by developing the initial team communications. When concerns arise, those individuals who are most familiar with the process are involved in the resolution of the issue. This approach results in issues being dealt with more efficiently, with less lost time, as the solutions come from personnel who will be directly involved in the outcome. There is often little need to involve upper management in order to address or resolve an issue.

This approach has also been used for a variety of remediation alternatives, for example, all goals (jointly) set by EPA, the State of Idaho, and DOE were met on or ahead of schedule, two (2) Records of Decision were signed in fiscal year 1995, and the removal and transport of NaK waste to Argonne was accomplished. Some sites have been closed via a preliminary scoping process, two interim actions have been completed, and four removal actions were completed. The "decision process" options (Track I and II, RI/FS, IA, RD/RA, Removal Action) allow a variety of remediation alternatives, dependent upon the type of waste and clarity of the project scope.

The approach can be applied to a well-defined project, or a not-so-well-defined project. For example, through the use of life-cycle baseline maintenance a project's technical, cost, and schedule components are refined as information becomes available, rather than to force-fit an undefined project into parameters which are likely to change on completion of scoping investigations.

Regularly scheduled Plan of the Week (POW) Meetings have been established to provide a forum for identifying and discussing technical and program management issues at a level at which they can be more rapidly and effectively dealt with by senior management.

Similarly, Remediation Project Manager (RPM) weekly POW meetings provide a forum for presenting, discussing, and resolving issues with regulatory management.

As an outcome of these meetings, white papers or guidance papers have been created to establish or clarify the ER position on such technical or programmatic issues as LDRD, land use, Eco Risk, and so on.

Disciplined Approach

The INEL ER Program uses a disciplined approach to manage the program, and each individual part of the program, as a whole. The disciplined approach takes advantage of all of the major approaches in the program:

goal oriented, teamwork, process oriented, flexibility, and incremental development.

The INEL ER Program manages its scope, schedule, and budget to an approved baseline. This baseline can only be changed by the change control process. The costs used in the program baseline and in changes to that baseline are controlled based on bottoms up cost estimates.

BENEFITS OF "THE INEL APPROACH"

Keys to Successful Baseline Development and Improved Program Management

Successful baseline development and management was achieved through the focused principles of teamwork, communication, and consensus building providing the program with unity. The baseline enables the program to function as a fully coordinated, cohesive, and mutually supportive organization. Frequently recognized benefits provided by the baseline are:

- Programmatic control via inter-contractor group(s) constantly working to resolve/eliminate issues; routine application of outcome-based approach/strategy
- "Program Level" Coordination and Control, implementing structured and consistent Configuration Management and Control of all three ER Baseline Elements
- Maximized Team approach - Seek to establish common understanding
- Up-front discussion and resolution/solution to process issues and barriers; i.e., Determination of what needs to happen - what needs to be in place

Tangible Results

A few of the challenges and successes of the INEL Environmental Restoration Program have included: a) completion of all enforceable milestones to date, b) acceleration of enforceable milestones, c) managing funds to reduce uncosted obligations at year end by utilizing greater than 99% of FY-95 budget, d) an exemplary safety record, e) developing a strategy for partial Delisting of the INEL by the year 2000, f) actively dealing with Natural Resource Damages Assessment issues, g) the achievement of significant project cost reductions, h) and implementation of a partnering charter and application of front end quality principles.

CONCLUSIONS

Share in order to experience improvement. Experience has shown us the benefits of increased understanding through the sharing of information. All successful processes and tools, in and of themselves, are valuable lessons to share. Always recognize that good communication and feedback are key elements in the continuous improvement process. The interaction and discussion that takes place in sharing information with others, is an invaluable means of renewing and validating a programs operating philosophies.

A successful program embodies the successful integration of these operating philosophies along with the program's cost, schedule, and technical work scope. Using this approach, all program elements can be established and maintained from a central point of control. From that standpoint, the process of maintaining a balance between the functional elements (cost, schedule and technical) and program goals and priorities is easily achieved.

LIVING WITH THE UK STRATEGY FOR THE DEEP DISPOSAL OF RADIOACTIVE WASTE IN A MORE COMMERCIAL ENVIRONMENT

John Mathieson
Allan Braby
UK Nirex Ltd

ABSTRACT

This paper provides an update on the UK program to dispose of low level waste (LLW) and intermediate level waste (ILW) in a deep facility in light of the outcome of two major Government reviews and a public hearing process considering the program's next phase. The reviews concerned the future of the UK Nuclear Industry and radwaste disposal strategy; the results of both were announced in the Summer of 1995.

The radioactive waste policy review concluded that disposal is the preferred option to indefinite storage, and that the program to implement it should go ahead as soon as practicable, to fulfil the requirement for a policy of sustainable development. The nuclear industry review looked at the structure of the industry, including the proposal that the nuclear generating utilities could be released from Government ownership and become privatized.

Nirex is the UK company responsible for implementing Government policy on LLW and ILW disposal and is owned and financed by the companies of the nuclear industry. Therefore the outcome of both reviews is of particular importance to it as it increasingly faces commercial pressures in providing a disposal facility for the nation's waste.

The paper summarizes the outcome of the reviews on LLW and ILW disposal policy and in particular covers the following points:

Nirex's plans to develop a deep disposal facility at Sellafield. The next stage for this is an underground rock characterization facility. The granting of permission to construct this is on the critical path for a repository and the proposal is currently undergoing a public hearing process;

Nirex's financing and organization structure and how this will operate in the future to be compatible with Government policies on disposal and the environment, in particular ensuring maintenance of the "polluter pays" principle. A description of the repository pre-financing arrangements and the potential tariff structure is given;

how a cost-effective deep repository system is being developed which is "optimized" in terms of:

technical requirements to deal with particular wastes; the cost of disposal;

safety - in light of revised proposals concerning the safety principles by which a future repository should be licensed and authorized to operate.

INTRODUCTION

Nirex, founded in July 1982, is the company in the United Kingdom responsible for providing and managing new national disposal facilities for solid ILW and some LLW. The Company's present shareholders are BNFL and Nuclear Electric plc, each with a 42% share, and Scottish Nuclear Ltd. and the Government Division of the UK Atomic Energy Authority, each with a 7% share. In addition, the Government owns a special 'Golden Share', which safeguards the Company's control of the repository site.

The Government, under independent advice from the Radioactive Waste Management Advisory Committee (RWMAC), has established national strategy

for the development of such facilities, and provided a legal framework within which safety and environmental impact must be assessed and examined in public. Since 1987, Government policy has been that ILW generally should go deep underground, and that the same facility could be extended to take LLW also, as a cost-effective alternative to developing a "greenfield" shallow site.

THE RADIOACTIVE WASTE REVIEW

Between May 1994 and July 1995 the UK Government carried out a review into radioactive waste management policy (the Radwaste Review), undertaken by the Department of Environment (DoE). That review was complementary to the Nuclear Review being carried out at about the same time by the Department of Trade and Industry, which considered the future of the nuclear industry in the UK.

The Radwaste Review encompassed three major aspects:

- a general review of radwaste management policy by DoE;
- a review of the requirements for the authorization of disposal facilities by Her Majesty's Inspectorate of Pollution (HMIP); and,
- a more specific review of the approach to site selection and human health criteria by a Study Group, drawn from the advisory bodies RWMAC and Advisory Committee on the Safety of Nuclear Installation (ACSNI).

The Study Group published its findings in early 1995 (1), the final conclusions of the Nuclear Review were published in May 1995 (2) and those of the Radwaste Review in July 1995 (3).

The outcomes are summarized as follows.

Ownership of Nirex

Under the Nuclear Review, parts of two shareholders (Nuclear Electric and Scottish Nuclear) may become privatized, and will be integrated into the existing Nirex shareholding structure.

This may mean that they will be able to exert "a substantial commercial influence on the affairs of Nirex". In order to ensure that its policies will be carried out, the Government has decided to retain its special share in the Company.

Regulatory System

This will be streamlined and revised guidance will be issued to potential disposers of radioactive waste. In addition, the Government will consider the responsibilities of the different regulatory bodies and other organizations for assessing the doses received by members of the public.

Policy Aims

The Government has concluded that the policy aims for radioactive waste management should be revised and updated to emphasis the respective roles of Government, regulators and producers and owners of waste, and apply the concept of sustainable development and its supporting principles.

Waste Categorization

Further consideration will be given to refining the categories of radioactive wastes in terms of their half-lives and activity, and to the proposal that short-lived ILW might be disposed of to the near-surface disposal facility at Drigg.

Early Applications for Authorization to Dispose

Developers of major projects may submit early applications for disposal authorizations at the same time that they seek full planning permission (under zoning laws) for the project. The regulators will then be able to make decisions on authorizations before major commitments have been made.

Disposal of Solid Waste

The Government believes that both estimates of risk and other factors of a more qualitative nature will need to be considered in determining whether a disposal facility is safe. However, it believes a risk target of 10-6 per year (fatal cancer or a serious hereditary defect) is appropriate. There should be no prescribed cut-off for the period over which risk should be assessed.

The Government welcomed the RWMAC/ACSNI Study Group's report on site selection criteria for radioactive waste repositories, but has reservations about some of the detailed proposals made.

Spent Fuel Management

The question of whether and when to reprocess spent fuel and decisions on the siting of dry stores for spent fuel should be for the commercial judgement of the operators.

High-Level Waste

The Government believes that geological disposal on land is the favored option for vitrified HLW once it has been allowed to cool and is putting in hand development of a research strategy.

Partitioning and Transmutation

The Government will continue to watch with interest the results of international research on partitioning and transmutation, but has no plans to initiate further development of its own.

The Nirex Repository

The Government continues to favor a policy of deep disposal rather than indefinite storage of ILW and considers it appropriate that Nirex should continue with its program to identify a suitable site. There would be no advantage to be gained from delaying the development of the repository itself and it should be constructed as soon as reasonably practicable.

Interim Storage of Intermediate and Low-Level Waste

Waste must be treated as necessary to improve storage conditions.

Decommissioning

Decommissioning nuclear power plants should be undertaken as soon as it is reasonably practical to do so, taking account of all the relevant factors. Segregated funds for decommissioning should be established for those parts of the industry which are privatized.

Waste Substitution

The Government reaffirms its policy that the wastes resulting from the reprocessing of foreign spent fuel should be returned to the country of origin. It accepts that this policy can be implemented by waste substitution arrangements which ensure broad environmental neutrality for the UK.

Import and Export of Waste

Radioactive waste should not be imported to or exported from the UK other than in the specific cases.

Small Users

The Government will not direct small users to particular routes for disposal of their radioactive waste, but will leave them free to make their own arrangements.

Research

Each of the component parts of the industry should continue to be responsible for research and development necessary to support their respective functions.

THE NIREX PROGRAM

Nirex's current focus is on surface-based geological investigations to determine the suitability of a potential deep ILW repository site near Sellafield, Cumbria, in north-west England.

Nirex's next step is to construct a deep underground laboratory (rock characterization facility, or RCF) shown in Fig. 1. This proposal is similar to other countries' deep experimental facilities and along with those being constructed at Yucca Mountain in the US and the Gorleben mine in Germany, is intended to be a site specific research facility. The Company's application for planning permission to construct the RCF, submitted in July 1994 (4), was refused in December 1994 by the Cumbrian Local Government. This decision has forced the Company to take its case to a public inquiry, the outcome of which is expected in 1997.

Fig. 1

When started, the RCF program will last at least 5 years. Subject to a successful outcome from these investigations, Nirex will submit a planning application for the 650m deep (below Ordnance Datum) waste repository (DWR) (Fig. 2), this will be the subject of a further public inquiry. The deep repository (5) will be capable of taking 200-275,000m3 of waste.

Fig. 2

FUNDING REQUIREMENTS

The DWR project is a typical large scale construction project as the bulk of investment is required upfront before any revenues can be earned. However the DWR is a fairly unique project due to the long construction timescales involved, which result in the accumulation of financing costs up to four times the actual cost of the project. The profile of cost and revenue cash flows is illustrated by the graphs Figs. 3 and 4 respectively.

The funding requirements of the DWR project are (1996 prices):

almost 2 bn between 1986/7 and the planned opening date;
between 10m to 20m per annum over an operating period of 45 years;
approximately 50m over a 5 year closure period; and
additional cover for unforeseen expenses in the post closure period.

Fig. 3

Fig. 4

CURRENT FUNDING ARRANGEMENTS

As noted above, Nirex is owned by four shareholders, all of which are currently in the public sector. Their relative shareholdings only broadly reflect their waste emplacement requirements on a volumetric or other attribute basis. The four shareholders currently pay for all Nirex costs on a monthly basis according to their respective shareholdings in the Company.

However, the four shareholders are not the only ones who have a requirement to emplace waste in the DWR, in all Nirex will have seven Customers. This raises an important issue of how to charge all seven Customers for emplacing waste on a fair and efficient basis. This also implies financially compensating those Customers who have been the sole providers of funds to Nirex in the past.

Nirex could recover costs by invoicing seven Customers as opposed to the current four based on the amount of space required in the repository. However, other parameters which reflect the activity or potential harmfulness of waste may be more appropriate.

It is possible to design a comprehensive invoicing system to fund the DWR project, however, this system of funding is difficult to adapt to

changing repository design, cost conditions and emplacement requirements. This had led to Nirex adopting a more flexible tariff mechanism to recover costs which is discussed in a later section.

EMPLACEMENT CONTRACTS

The Emplacement Contracts will form part of the legal framework around which any future form of funding will be based. The Emplacement Contracts will essentially

- secure the long term funding of the DWR project by requiring Customers to sign formal agreements to finance their share of costs over a specified period;
- enhance the economic viability of the project, through the achievement of repository design optimization;
- introduce more market based disciplines to the project; and
- increase accountability to Customers by making the activities and cost base of Nirex more transparent.

The contracts will therefore:

- allow Customers to gain increased influence in the general affairs of Nirex;
- increase certainty from the project's viewpoint by securing funds;
- improve accountability for the Government through greater transparency; and
- impose 'value for money' for Nirex Customers and Shareholders.

These contracts will be essentially on a take-or-pay basis, whereby Customers will still be liable to pay for any space (used or not) for which they are committed. Customers will be given the opportunity to change their initial bids in order to provide a situation whereby all parties are agreed and the DWR costs are optimized - based on the latest technical information, before the contracts are signed. Customers who refuse to sign Emplacement Contracts will not be guaranteed use of any Nirex facilities for disposing of their waste in the future.

Customers requiring more space in the future will not have any guaranteed supply from Nirex, as Nirex does not intend to retain any spare capacity. Instead, the Customer will be obliged to purchase space from others with surplus capacity. If Nirex extends the DWR for any additional requirements; even though the marginal costs of DWR extension are lower than the tariff, the Customer requiring space will be liable to pay the full tariff. Any additional revenue gained by Nirex will be distributed to other Customers in an equitable manner.

THE NIREX TARIFF

The Tariff

A tariff has two major advantages:

i) it is a self balancing funding mechanism which can allocate funds on an equitable basis between initial participants; and

ii) it enables cost savings to be apportioned in a fair way and therefore provides an incentive to achieve cost savings and value for money for Customers through optimizing the DWR project.

The key principles underlying the tariff structure are:

- securing financeability by charging tariffs which recover the full lifetime costs of the project, including financing costs - this is achieved through the application of a discount rate within the tariff calculation;
- to allocate costs amongst customers in a fair and equitable basis;
- to derive tariffs which reflect the cost of emplacing different waste streams and therefore provide efficient pricing signals to Customers; and

designing the tariff to be simple enough to be readily understood by all Customers.

However, it is not practically possible to pursue these objectives in a purist manner as some may conflict. For example, efficiency implies the charging of cost-reflective tariffs which in turn suggests a marginal cost pricing regime. However, in the case of the DWR project, approximately 50% of all costs are currently classed as common and therefore cannot be recovered if the principle of efficiency is pursued to an extreme.

Cost Drivers

The Nirex cost allocation work forms the basis upon which to charge for costs incurred, in an efficient manner. This is achieved by determining the amount each Customer is liable to pay by relating charges to the cost drivers of the project. Based on the current DWR design, Nirex has identified the following five main cost drivers:

- the number of packages to be emplaced;
- the displaced volume of waste to be emplaced in unshielded vaults - this determines the size of vaults required to be excavated;
- the displaced volume of waste to be emplaced in shielded ILW/LLW vaults;
- the amount of long-lived waste to be emplaced; and
- emplacement of specific 'problem' radionuclides - direct charges for any projects which have been conducted to analyze specific radionuclides such as Chlorine 36 and Iodine 129.

Tariff Parameters

The tariff parameters which are based on the above cost drivers are listed below:

a - a general charge per package to be emplaced; plus either:
b - per m3 of vault space for LLW or shielded ILW package; or
c - per m3 of vault for unshielded ILW package.

Plus:

d - per TBq of long-lived radionuclide content;

Plus:

e - per MBq of 'problem' radionuclides

Plus:

any surcharges identified in the future.

In choosing Tariff Parameters, Nirex has recognized that the calculation of tariffs should not impose extra burdens on Customers over and above those already needed by Nirex for technical/safety reasons. For example, there are cases where waste has been stored in such a way that the Customer cannot be exactly sure what a particular package contains. However, at emplacement Nirex must be able to satisfy itself that it has a justifiable record of what each package contains. Whether package contents are known precisely, or whether they are estimated, the payments under the tariff will be based on this emplacement record requiring no additional effort on the part of Nirex Customers.

If at any stage the measurement of any of the parameters included in the tariff ceases to be needed, then it is not necessarily the case that its measurement should continue simply to enable the tariff to be calculated. The tariff is intended to be cost reflective and as such draws on existing technical waste classification measures. If these change it might well be appropriate for the tariff structure to change as well, recognizing the new technical view of which waste attributes are most

important in driving the DWR program. This will be handled by the change control mechanism in the Emplacement Contracts.

With regard to the allocation of costs between long-lived waste packages, Nirex has chosen activity (measured in TBq) as its base measure but alternatives are being reviewed The problem with using activity is that it may complicate negotiations as agreeing the reference time will be key.

The year of maximum post-closure risk may be an alternative method of allocating long-lived waste costs. This will discriminate against those radionuclides which are most influential in terms of success of the safety case. However, peak risk years are likely to be subjective in choice as they are determined by modelling different scenarios in the future. Again this is likely to lead to complex negotiations between Nirex and Customers due to the subjectiveness of the measure.

Common costs of the project may be recovered by pro-ratering them across all or some of the tariff attributes which itself be sensitive to the method of pro-ratering employed.

Surcharges

In addition to the tariff parameters which reflect the DWR cost drivers, a system of penalty payments or surcharges for waste packages which fail to meet Nirex requirements is envisaged. Under this structure a 'standard package' will bear no charge with respect to these attributes but any packages which exceed a given norm for these characteristics will be liable for an additional charge. This is designed to reflect those attributes which do not influence the project program or the base design and therefore should not form parameters in the tariff itself, but would cause operating or safety case difficulties. Imposing a surcharge will discourage such non-conforming packages from being presented for emplacement. Therefore, surcharges are consistent with the tariff principle of efficiency as only the additional costs associated with a 'non standard' package, is charged to that package. An example may be a surcharge on a package with excessive heat output as it may require specialist handling equipment.

The advantage of this structure is that surcharge items need not be resolved at this stage. The tariff will be calculated to recover program costs using the basic parameters: any revenue from surcharges being additional. The structure of surcharges will be developed as more information becomes available, and their level can be determined when more information on the technical implications of non-conforming packages is known.

Advanced Funding

As Customers will only be charged at the time of waste emplacement, Nirex requires advanced funding in the period up opening in order to cover its costs. The amount of advance payment that Customers are allocated will be calculated from certain waste attributes which are present in their waste emplacement schedules. These waste attributes which are identified by the cost drivers and tariff parameters, include the number of TBqs of long-lived waste and the number of packages of shielded and unshielded waste to be emplaced.

Advance payments are calculated in the following manner:

- firstly, each Customer's share of attribute is calculated;
- secondly, Customer shares of each attribute are multiplied by the total cost cash flows of each attribute in order to determine each Customers' cost share for all attributes;

the addition of cost cash flows for each attribute gives the total cost payable by each Customer each year. This is the amount of advance payment that each Customer will be expected to pay in each year to opening;

the proportion of advance payment allocated to each attribute will be simply the proportion of total cost associated with each attribute each year, e.g. if attributes A, B and C account for 60%, 20% and 20% of Customer.

The tariff aims to make Customers indifferent between funding in advance and receiving rebates in the future. The tariff will accrue advanced payments at a pre-determined rate of return that reflects project risk and repay them to appropriate Customers through a rebate at the time of emplacement.

Customers who choose not to pay in advance will be liable to pay the full tariff at the time of emplacement. This tariff will be determined by the rate of return (which will be the same as that for accrued advance payments), as the rate of return is equitable to the cost of borrowing. This break-even implies that the unit price payable for each tariff parameter is set such that the discounted value of the revenue stream associated with that particular attribute equals the discounted value of the cost stream allocated to it. This ensures that financing costs incurred as a result of the mismatch in timing between expenditure and receipt of income are recovered.

Payment Scenarios

The two payment scenarios are summarized below:

advance payment plus emplacement tariff minus rebate - where the rebate equals advance payment adjusted to account for project risk at an appropriate rate of return;

zero advance payment plus emplacement tariff minus zero rebate;

These are consistent with the principles of fairness and simplicity. The overall DWR project share allocated to each Customer may be attained by discounting each Customer's overall tariff payments.

The Rate of Return chosen for the project is key to determining whether Customers elect to pay in advance. If the rate is seen to be too low, then certain Customers may elect to invest in other projects rather than in the DWR project in order to earn a higher rate of return. However, it must be stressed that the project is a joint venture between Customers and if some of the main Customers elect not to pay in advance for financial reasons, then the project may not progress as funding from financial institutions is unlikely to be a feasible alternative.

CONCLUSION

Notwithstanding the requirement to face a public inquiry for the RCF, Nirex is making steady progress on repository development at Sellafield. This is not only in the scientific and technical areas but also in that of financing the project. A successful and early outcome to the next stage of Nirex's program at Sellafield, the RCF, will keep the Company on track for developing a deep repository early next century.

PENNSYLVANIA'S LAND RECYCLING PROGRAM: IMPLICATIONS FOR CERCLA'S REAUTHORIZATION AND PROGNOSIS FOR SIMILAR PROGRAMS IN OTHER STATES

Carl S. Pavetto
Systematic Management Services
Germantown, MD 20874

ABSTRACT

Two of the biggest problems with the federal Comprehensive Environmental Response, Compensation and Liability Act ("CERCLA") are the policy that every site that is cleaned-up under CERCLA needs to be cleaned up to pristine conditions and the potential for virtually unlimited liability for parties connected with a contaminated site. As a practical matter, parties find that the stakes are often so high as to induce them to choose litigation first instead of going directly to cleanup. In addition to these issues, there is also the problem that CERCLA, being of national scale, is devoted to the cleanup of the worst sites. Many more sites -- the "brownfields" -- do not rise to the level of inclusion on the National Priorities List. The cleanup of these sites remains within the primary province of the states.

A number of states are increasingly recognizing the benefits to be gained from the cleanup of brownfields and putting these idle properties into productive use. One such state is Pennsylvania. With the adoption last summer of progressive legislation for brownfields remediation, Pennsylvania is now on the forefront of this environmental issue. Pennsylvania's land recycling program, as it is called, provides solutions to two of the problems that have hindered the effectiveness of CERCLA. First, Pennsylvania's program deals with the issue of "how-clean-is-clean?" by defining clean as remediation that meets any of three cleanup standards categories -- background, site-specific or state-wide health-based -- and it allows the choice of standard and level of cleanup to be determined by the proposed end use for the property. Second, Pennsylvania's program absolves parties who cleanup according to the program guidelines from further liability

Pennsylvania's handling of the "how-clean-is-clean?" and the liability issues promises to be a great stimulus to brownfields remediation in the Commonwealth and can also provide a model for brownfields remediation programs in other states and for amending CERCLA as well.

INTRODUCTION

Pennsylvania's Act 2 takes a common-sense approach to brownfield remediation. The approach addresses two of the major disincentives that had existed under Pennsylvania's previous land remediation policies and which also have created problems and delays for cleanups under the Comprehensive Environmental Response, Compensation and Liability Act ("CERCLA"). These two disincentives are: 1) the requirements and policies that would return the land to pristine condition regardless of the end use and 2) potentially never-ending liability for responsible parties. Pennsylvania's program -- informally called the land recycling program -- purports to solve these two problems. Act 2 provides for standards that

by law are protective of human health and the environment and which also allow for the consideration of future uses to which the land would be put. The Act provides owners or developers with cleanup standards based upon risk and end use. In addition, Act 2 provides for an end to further environmental liability when the remediation conducted by the parties attains the agreed-to cleanup standards and is certified by the Pennsylvania Department of Environmental Protection ("DEP").

The full program is actually authorized in three statutes. Act 2 is the land recycling program; Act 3 releases lenders from liability; and Act 4 provides funding.

PENNSYLVANIA'S APPROACH TO BROWNFIELD REMEDIATION

Pennsylvania's approach to recycling brownfields into productive use has four main and several additional elements. The main elements are:

- uniform cleanup standards based on health and environmental risk
- standardized administrative review procedures so that proposals submitted can be better prepared and reviewed and more readily approved
- releases from liability when the cleanup standards are met, and
- financial assistance.

Among the additional elements of the program are two that are designed to further expedite cleanups.

- elimination of the requirements for state and local permits for remediation activities undertaken pursuant to Act 2, and
- provisions for cleanups in "Special Industrial Areas" that limit the cleanup requirements to performing a baseline environmental assessment and remediating only direct and imminent threats.

Uniform Cleanup Standards Act 2 establishes three types of cleanup standards that, when achieved, will allow responsible parties to obtain the release from liability. These are:

- background
- state-wide health-based, or
- site-specific standards based on environmental and human health risks.

Act 2 became effective in Pennsylvania on July 18, 1995. With Act 2's effectiveness, both the opportunity to select the cleanup standards for a contaminated site and a mechanism for absolving the parties from future liability came into existence. The standards available for a site fall into three categories: 1) background, 2) state-wide health-based, or 3) site-specific. The background and the site-specific options became immediately available on the effective date of the Act. The existing state-wide standards in effect for soil (developed under the predecessor Hazardous Sites Cleanup Act) and groundwater (developed under the Clear Streams Law) also became available under Act 2 on an interim basis. The Act, however, directs the Pennsylvania Department of Environmental Protection ("DEP") with assistance from the Cleanup Standards Science Advisory Board ("CSSAB" or "Board") to propose a set of permanent state-wide health-based standards by July 18, 1996, and to adopt the permanent standards by July 18, 1997. Thus, the final, permanent state-wide health-based standards are being developed by regulation over a two-year timeframe. The key to the program in Pennsylvania is that a demonstration by the parties that a site has been remediated according to the pre-selected standard and a certification from the PA DEP will entitle the parties to a release from future liability for the site.

Anyone who wishes or is required to clean up a site and wants to obtain the liability protection must select and obtain compliance with any one

or combination of the background, state-wide health-based, or site-specific standards.

Background. The definition of "background" under Act 2 is the "concentration of a contaminant that is present at the site but is not related to any release of contaminant at the site." Thus, a developer who elects to clean up a site to background must document that the concentration of any contaminants remaining after the cleanup are not related to any releases of contaminants at the site. Act 2 therefore accommodates the situation where contamination could be present because it has been released from an off-site location. Anyone who chooses to use the background standard must meet background for each contaminant in each environmental medium. As mentioned, however, a person could choose to use the background standard for one contaminant in a medium and could also select either the state-wide health-based or the site-specific standard for other contaminants.

Site-specific. Anyone who chooses to use the site-specific standards can develop a cleanup level for the specific site based upon the contaminants, exposures and conditions unique to the site. Under Act 2 for the site-specific standards, certain guidelines must be followed depending on the type of contaminant and the medium involved. For example, for carcinogens, the cleanup level for soil and groundwater are to be established at levels that represent an excess cancer risk between one-in-ten-thousand and one-in-one-million. For toxic chemicals other than carcinogens, the cleanup level must be such as to prevent deleterious effects to the exposed population.

State-wide Health-based. Anyone who chooses to use the state-wide health-based standards can depend, during the interim period (until the permanent state-wide health-based standards are adopted), on the existing groundwater and soil standards. The permanent state-wide regulations under development by the CSSAB and DEP will provide a list of cleanup levels for various contaminants. These "medium-specific concentrations" ("MSCs") are the concentrations of contaminants associated with a specific environmental medium for potential risk exposures. Different exposure potentials such as residential or industrial settings will be reflected in different cleanup concentrations providing for equivalent levels of human health protection.

Thus, what the final state-wide health-based standards will do is round out the statutory requirements for the establishment of three categories of standards governing brownfield remediation in Pennsylvania. The availability of state-wide health standards, together with the opportunity to use background concentrations, site-specific standards based on risk, or a combination of standards, assures optimum flexibility on the part of brownfield site developers for obtaining the release from liability that is the impetus for this program.

Standardized Review Procedures

Legislators in Pennsylvania recognized the benefits to be gained from uniform submission and review procedures and incorporated uniform processes in Act 2. This uniformity makes it easier for site developers or their consultants to prepare submissions and to follow the steps necessary to remediate a site so as to obtain the liability protection. It also provides predictable opportunities for the public, local governments and others to participate in the remediation process.

While there is some variation in the review procedures depending upon the category of cleanup standards, the basic procedures for each of the

categories is uniform. The step that begins the process is the same for each type of standard -- filing a Notice of Intent to Remediate ("NIR") with the Department of Environmental Protection. Thus, the NIR must be sent to the PA DEP regardless of whether the developer is proposing cleanup to background, state-wide health-based, a site-specific standard or any combination thereof. Upon receipt of the NIR, the PA DEP will publish an acknowledgment in the Pennsylvania Bulletin.

The developer must also send a copy of the NIR to the municipality where the site is located and a summary must be published in a local newspaper.

The next step in the process is where the procedures differ depending on the standard selected. Except for the site-specific standard, there is no provision in Act 2 that requires DEP's prior approval for a remediation plan. However, prudent developers who have selected background or state-wide health standards will obtain DEP's concurrence before beginning the actual remediation since DEP's certification at the end of the process is required for the parties to obtain the liability protection.

For remediation designs based on site-specific standards, the developer must prepare and submit site assessment and remediation proposal documents which are subject to public input and DEP approval. These documents must be sent to the municipality and notice of availability must be published in a local newspaper and in the Pennsylvania Bulletin.

The additional steps begin with a thirty-day public comment period which also gives the municipality the opportunity to be involved in the development of the remediation and reuse plans for the site. Moreover, if the municipality requests a public involvement plan, the parties must develop and implement such a public involvement program. The requirement for a public involvement program carries with it additional obligations. That is, each time a remedial investigation report, risk assessment report, cleanup plan or final report is prepared, notice of its submission to DEP must be provided to the municipality, a notice summarizing its findings and recommendations must be published in a local newspaper, and the reports must also include the comments submitted by the municipality or the public and the developer's responses to those comments.

As described above, the Notice of Submission of the Final Report must be sent to the municipality, published in a local newspaper and published in the Pennsylvania Bulletin. Finally, where the background or statewide health-based standards are used, the PA DEP has sixty days to review the final report and either approve the report or respond with a letter of deficiency. If a site-specific standard is involved, the PA DEP has an additional thirty days -- for a total of ninety days -- to act.

These uniform procedures are designed to add to the administrative aspects of the program a degree of certainty that is intended to expedite review and approval and complement the certainty on the technical side that comes from having uniformity in the technical standards.

Limitation or Release of Liability

The key provision in Pennsylvania's land recycling laws is the opportunity for owners and developers to obtain a release from future liability. When the DEP approves the final report, i.e., determines that the site has been remediated according to the standards and the procedures in Act 2, the release from liability takes effect. A companion law, Act 3, extends the liability protection to project financiers and fiduciaries.

The requirement for final certification by DEP that a site meets the standard depends on the cleanup standard(s) chosen and carries with it certain restrictions. For all of the standards, attainment must be demonstrated by the collection and analysis of representative samples for the environmental media of concern viz., soils and groundwater. Moreover, the vehicle for obtaining the release from liability, common for all standards, is the final report as described above. There are important differences, however, and these are as follows. When background is the cleanup standard, institutional controls, such as fencing or land use restrictions, may not be used and a deed notice is not necessary. When a state-wide health-based standard is the chosen standard, institutional controls may not be used and whether deed notice is required depends upon the projected end use of the site -- deed notice is not necessary for sites meeting the residential health standards but is required where non-residential health standards (exposure factors) were used to comply. Finally, when the site-specific standard is used, deed notice is required and this notice must indicate whether residential or non-residential exposure assumptions were used in developing the site-specific cleanup standards.

Financial Assistance

The program has two avenues for financial assistance. These are funds established under Act 2 and Act 4 and administered by the Pennsylvania Department of Commerce.

Act 2 establishes the Industrial Sites Cleanup Fund. This fund is available to help innocent persons conduct voluntary cleanups. Through the fund, grants or low-interest loans are available for 75 percent of the cost of completing an environmental study and implementing a cleanup plan. Act 4 provides a funding mechanism through the creation of the Industrial Sites Environmental Assessment Fund.

Additional Program Elements

Among the additional components that enhance the workability of the program are the provisions that state and local permits are not required for remediation work under Act 2 and the provisions for sites in "Special Industrial Areas." Special Industrial Areas are either orphan sites or sites in "Enterprise Zones." For these sites, developers need comply only with the requirement to remove the imminent threat to obtain the liability protection. In other words, they need not comply with the three types of standards. For example, a developer need only remove leaking drums of hazardous material if these drums constitute the imminent threat.

ISSUES AND PROGNOSIS FOR OTHER STATES

The promise of Act 2 is that by providing a mechanism for parties to limit their liability it will provide the necessary encouragement to stimulate a high degree of brownfield remediation in Pennsylvania. The program provides a realistic approach to the remediation of sites that are too contaminated for further development but not enough to warrant a place on the National Priorities List.

As with any such statute, Act 2 does not provide answers to all of the implementation questions. Therefore, a number of important questions remain to be answered in order for the Act to be implemented successfully. These remaining questions not only produce challenges for the implementers in Pennsylvania but also serve as an indicator to legislators and implementers in other states of the types of issues with which they will likely be confronted.

Accordingly, this section of the paper is devoted to a discussion of several of the most important implementation issues that have been spawned by Act 2 in Pennsylvania. These issues are broad, if not universal, in their application as well as being difficult to resolve. First, however, it is important to present a brief description of the implementation of Act 2 in Pennsylvania.

It was discussed above that a key provision of Act 2 is the establishment of three categories of remediation standards -- background, site-specific and state-wide health-based. In the implementation phase, use of the background standard is a matter of demonstrating what background is (not necessarily an easy determination) and then demonstrating after remediation that the standard has been met on the target site. The site-specific approach, in a similar fashion, requires the development of an individual cleanup standard for the site based on risk assessment and the demonstrating that it has been achieved from the cleanup. At this writing, these two categories of standards are fully available for implementation -- in other words, the liability protection can now be obtained through either one or both of these two categories of standards. The full availability of the state-wide health-based standards, however, must await the development and adoption of the permanent standards by the Pennsylvania DEP with the participation of the Cleanup Standards Science Advisory Board. As mentioned previously, the Board's role is to assist the DEP in developing the state-wide health standards. Moreover, the Board's charge is to propose the standards within one year and adopt the standards within two years of the effective date of Act 2.

The current work of the CSSAB is particularly instructive because the Board is confronted with implementation issues that are universal in their application as well as being timely and difficult to resolve. By examining the workings of the CSSAB it is possible to gain an understanding of implementation issues that are not unique to Pennsylvania's program. How the Board and the DEP resolve these issues can provide very useful information in other venues. Thus, the following list of issues has been drawn from the list of major issues that has been developed by the CSSAB in Pennsylvania.

These issues were selected for discussion in this paper because of their importance to the successful implementation of Act 2 in Pennsylvania as well as their potential for broad-based application to other states' programs. The issues are:

1. What is a carcinogen?
2. Does a paucity of toxicological data for a particular contaminant absolve the regulators from the requirement to establish a standard.
3. Does the statute require and, if it does, how can ecological risk be incorporated into the development of remediation standards?
4. What is an aquifer?
5. How does a party demonstrate attainment of a numerical standard?

Taken in the numbered order, these issues are discussed below.

What is a Carcinogen?

Act 2 in Pennsylvania defines a carcinogen as a "chemical, biological or physical agent defined by the Environmental Protection Agency as a human carcinogen." The problem is that this reference to "human carcinogen" does not make it clear whether Act 2 is referring only to the U.S. EPA's Class A human carcinogens or to the suspected and possible human carcinogens in Classes B and C. This issue is not mere semantics; it has added significance because it is related to the second issue.

While it seems likely that the Pennsylvania legislature meant to include all of the chemicals in EPA's Classes A, B and C, this is not clear. Consequently, a reasonable interpretation of the definition in Act 2 would indicate that "human carcinogen" pursuant to Act 2 means the known carcinogens. To date, much discussion among the members of the CSSAB has been devoted to this issue.

It is clear that other states confronting this issue need to provide for the clarity that is lacking in Act 2 in Pennsylvania for the definition of human carcinogen.

What is the Effect of a Lack of Toxicological Data for a Contaminant?

For many chemical contaminants there is a lack of toxicological data. This is a serious problem for the implementers who are charged with developing the state-wide health standards. Simply stated, the issue is that the lack of a standard for any particular chemical contaminant means that there would be no mechanism for that contaminant in Pennsylvania by which a party can obtain the release from liability that is key to the effectiveness of the program. Having no mechanism for a full limitation of liability is clearly not in keeping with the spirit of the Act.

The lack of toxicological data for chemical contaminants is a universal problem. In Pennsylvania, the problem is intensified because of the way that Pennsylvania has established the mechanism for obtaining the release from liability. Any other state that would take a similar approach would be confronted with the same problem.

Does the Requirement to Incorporate Risk Include Ecological Risk?

As discussed above, Pennsylvania's approach to establishing the state-wide health-based standards is through an advisory board charged with providing assistance to the DEP. The essential guideline in Act 2 for developing the state-wide standards is to determine "the appropriate risk factors as needed to implement the provisions of [the] Act."

Thus, an issue that rises immediately to the fore is whether "appropriate risk factors" includes ecological risk. One of the policy declarations of Act 2 states that "cleanup plans should be based on the actual risk that contamination on the site may pose to public health and the environment." It should be clear to other states from Pennsylvania's experience that they may want to assure that their legislation clarify the ecological risk component. Moreover, if ecological risk is to be included in the development of the state-wide standards, the next issue is how to do it.

Groundwater Versus Groundwater-in-Aquifers

While this issue arises as a consequence of the wording of Pennsylvania's statutory definition of aquifer, it is not an issue of mere semantics.The legislative history of Act 2 clearly contemplates, as well as remediation of groundwater in aquifers, the remediation of contaminated shallow groundwater -- that is, groundwater that is by definition not in aquifers. Act 2 defines "groundwater" as "water below the land surface in a zone of saturation." On the other hand, the Act defines "aquifer" as a "geologic formation, group of formations or part of a formation capable of a sustainable yield of significant amount of water to a well or spring."

A major problem arises because of the way the statute requires the consideration of the inhalation factor in the establishment of state-wide remediation standards for "groundwater". For groundwater -- that is, groundwater not in an aquifer -- the development of an exposure factor that accommodates exposure through inhalation would incorporate inhalation factors much longer in duration than those for contaminated

groundwater in aquifers. The reason is that exposure through inhalation of vapors from aquifer waters would be expected to occur when the water is actually being used -- drinking, showering, cooking, etc. -- while exposure to inhalation from groundwater-not-in-aquifers can be expected to occur any time. The likely anomalous result is that the state-wide standard for groundwater-not-in-aquifers could be more stringent than the standard for water in aquifers.

One possible solution to this problem, discussed by the CSSAB, is to develop dual standards for each contaminant in groundwater -- one for groundwater-not-in-aquifers and a separate standard for groundwater in aquifers. The prospect of the Board's having to develop dual standards, particularly within the one-year time period allowed by Act 2, is daunting. It is clear, however, that this is a problem that other states would want to avoid.

How Should Attainment of a Numerical Standard be Demonstrated?

This issue is universal. In Pennsylvania, Act 2 provides that attainment (regardless of the standard) "shall be demonstrated ... through the application of statistical tests ..."

The problem confronting the CSSAB is that while its charge is to develop statistical tests only for the state-wide health-based standards, its work is actually the vanguard for demonstrating compliance with any of the other standards pursuant to Act 2. Whatever statistical methods the Board develops, they must be consistent with accepted statistical methods. In addition, it is to be expected that the Board's work will be applied across-the-board to demonstrate compliance.

As of this writing, the CSSAB has identified a range of options for an overall approach to specifying statistical demonstration methods. This range is from complete reliance on available guidance to developing very prescriptive statistical demonstration methods. Also as of this writing, the CSSAB has opted for a middle-of-the-road approach that involves a combination of developing anew a statistical model for the use of those who want to use it and also adopting existing guidelines developed to implement the predecessor to Act 2, the Hazardous Sites Cleanup Act.

IMPLICATIONS FOR THE REAUTHORIZATION OF CERCLA

The anticipated economic and environmental benefits from programs that encourage brownfield remediation are clear. A key question is whether the approach to brownfields remediation in Pennsylvania or any other state can have implications for the reauthorization of CERCLA. While CERCLA was up for reauthorization in 1994, the U.S. Congress was unsuccessful in reaching agreement to amend those aspects of CERCLA that have been widely criticized -- the provisions for joint and several liability, the provisions for retroactive liability, and the lack of a mechanism to tie the level of remediation to the end use of the property. The land recycling program as enacted in Pennsylvania and similar programs enacted and being considered in other states can provide valuable information for Congress to deliberate. Of course, the key provisions that promise to make Pennsylvania's experience a success are the opportunity for the parties to absolve themselves from liability and the mechanisms -- i.e., the three sets of standards -- established for doing so. Whether Congress is ready to adopt such radical changes to CERCLA remains to be seen.

SUMMARY AND CONCLUSION

In Pennsylvania, Governor Tom Ridge and his administration have enthusiastically backed Act 2 and have placed a considerable amount of stock in the implementation of the program. The CSSAB, a board of

thirteen members, has been aggressive in trying to meet its July 1996 deadline for producing the proposed state-wide health-based standards. By these measures, the program promises to be successful.

In reality, the success of the program will also depend upon the work of many sectors -- developers, municipalities, lenders, regulators and the public. Perhaps the most important factor for the effective implementation of the program is that each of these sectors has a vested interest in its success. Everyone stands to gain from a successful program. Moreover, as the program results in the cleanup of contaminated sites across Pennsylvania, both the economic sector and the environment stand to benefit. Thus, it can truly be said that Pennsylvania's land recycling program promises a win-win situation for the Commonwealth.

FINAL DISPOSAL OF LOW AND INTERMEDIATE LEVEL WASTE THE NORWEGIAN CONCEPT: A COMBINED STORAGE AND DISPOSAL FACILITY

Anita A. Srlie
Norwegian Radiation Protection Authority
P.O. BOX 55
N-1345 sters, NORWAY

ABSTRACT

There are no nuclear power plants in Norway, only two research reactors. The Institute for Energy Technology (IFE) is operating these reactors. One is in Kjeller, 25 km east of Oslo, the other is in Halden, 110 km south-east of Oslo. IFE is responsible for all waste management actions in Norway and operates a waste conditioning facility at the Kjeller site, where all the conditioned waste is stored. Almost all conditioned waste in Norway is packed in 210 l steel drums.

The process to select a site for the disposal of low and intermediate level waste in Norway has been under way since 1989, when a committee was appointed for this purpose by a royal decree. The committee focused principally on disposal in existing abandoned mines and railway tunnels, and in March 1991 recommended that the abandoned Killingdal mine, in mid-Norway, should be used for disposal. A second alternative was to construct a new facility close to the waste conditioning facility which is located in Kjeller, outside Oslo.

In 1992, The Directorate of Public Construction and Property (Statsbygg) prepared its impact assessment for a repository for Norway's low and intermediate level waste in accordance with the Planning and Building Act. Three sites, the Killingdal mine together with Kukollen and Himdalen, both located close to the Kjeller area, were evaluated. The steering committee recommended Himdalen as the preferred site. The decision was made by Parliament in April 1994 that a combined storage and disposal facility should be built in Himdalen.

It is planned to build the facility in a hard rock formation about 50 m below the surface. The facility will be accessible through a slightly declining tunnel. Some plutonium bearing waste will be stored in a separate room in the facility. Before the year 2030, based on the knowledge and experience gained during the operational phase, a decision will be made whether the storage facility should be transformed into a repository or the plutonium bearing waste should be retrieved.

The operation is planned to start in 1996/97 and closure is foreseen for the year 2030.

INTRODUCTION

After the merging of the National Institute of Radiation Hygiene and the Norwegian Nuclear Energy Safety Authority in April 1993, the Norwegian Radiation Protection Authority (NRPA) was formed as regulatory body in Norway for both radiation protection and nuclear safety. NRPA is divided into four departments, Nuclear Safety Department, Environmental Protection Department, Health Physics Department and Radiation Medicine Department. The Nuclear Safety Department is, among other things, responsible for the supervision concerning the safety and the radiation protection at the Norwegian research reactors, including the waste management and transportation of nuclear material.

In 1989, a committee was appointed by the government to investigate possible solutions for final disposal of all the Norwegian LLW and ILW (1).

In 1992, an Impact assessment was performed including three possible sites, with a recommendation for one of them. This was an engineered rock cavity facility, 25 km from the Kjeller waste conditioning plant (2).

During the Parliamentary committee work it was decided that it should be a combined storage and disposal facility, with storage of the plutonium bearing waste and disposal of the short lived waste.

THE NORWEGIAN NUCLEAR PROGRAM AND THE ORIGIN OF THE NORWEGIAN RADIOACTIVE WASTE

Norway does not have nuclear power plants, although there are two research reactors.

The Institute for Energy Technology (IFE) operates these two reactors located in Halden, 110 km south-east of Oslo and in Kjeller, 25 km east of Oslo. Figure 1 shows the sites on a map of southern Norway. IFE is an industrial foundation funded from the national budget and from commercial research programs. The main data of the two reactors are:

1. Halden Boiling Heavy Water Reactor (HBWR):

Max. Thermal output: 20 MW
Coolant: Heavy water
Moderator: Heavy water
Fuel: Enriched uranium dioxide
Cladding: Zirconium
Test fuel: Both uranium dioxide and MOX fuel is used
Started: 1959

Main research areas at the Halden reactor are reactor safety, technological research and development. Fuel testing and research on man-machine interactions are two important tasks.

The waste is mainly ion exchange resins. Tested fuel elements are returned to their owners.

2. JEEP II, at Kjeller:

Max. Thermal output: 2 MW
Coolant: Heavy water
Moderator: Heavy water
Fuel: Slightly enriched uranium dioxide
Cladding: Aluminum
Started: 1967

JEEP II is used to produce pharmaceutical products and irradiation services for medicine, industry and research. Neutron beams from the reactor are used to study the fundamental physical characteristics of solids and liquids.

Fig. 1

The origin of the Norwegian waste is summarized below:

Laboratory scale fuel reprocessing plant (operation 1961 - 1968)
liquid fission products and decommissioning waste

Examinations of irradiated fuel in the metallurgical laboratory II
cutting and grinding waste

Halden reactor
ion exchange resin

Isotope (pharmaceutical) production
all kinds of laboratory waste

Research
waste from IFE and other research institutions

Medicine
tracer examinations

Industry
solid sources from industrial applications

Scale deposits on production equipment from offshore industry in the North sea,
low specific natural activity.

Exit signs and ionic smoke detectors

Decommissioning
when the two research reactors are going to be closed down, this work will result in various types of LLW and ILW.

WASTE AMOUNT AND RADIOACTIVITY CONTENT

The low and intermediate level waste in Norway is presently conditioned and stored at IFE, Kjeller. Most of the waste is packed in 210 l steel drums, but also 800 l boxes are in use. An equivalent of about 2000 drums is in store.

In 1970 it was decided to bury the waste drums (210 l) that had been generated in Norway until then at the Kjeller site. 1013 drums and some other large waste components were disposed of in a 4 m deep trench, stacked in two layers and overfilled with 2 m of clay. There are no engineered barriers. About 230 of these drums contains solidified liquid waste from the laboratory scale fuel reprocessing plant at Kjeller. The liquid was mixed with concrete and placed into the steel drums with an inner coat of polyethylene (3). This waste will be retrieved, reconditioned and transferred to the new storage and disposal facility when it is available.

Between 50 and 100 drums are produced each year. About 80 per cent of the waste volume originates from the activities connected to the research reactor program, while industry and medicine produce about 10 per cent each.

Up to the year 2030 it is estimated that an equivalent of about 10 000 drums of low and intermediate level waste with a total activity of approximately 200 TBq including about 50 g of plutonium will have been generated.

SITING AND LICENSING PROCEDURE FOR A REPOSITORY

The siting process for a repository started in 1989 when a committee was appointed by the government. This committee prepared a report that described the waste and discussed safety criteria and principles for the disposal of all the LLW and ILW in Norway (1).

In its search for possible solutions for the disposal of Norwegian waste, the committee assessed existing rock cavities (mines, road tunnels, railway tunnels a.s.o.). The construction of a new installation specially designed for the purpose of disposal was also considered. The main

conclusion was to construct a repository in the abandoned mines at Killingdal near Rros, 430 km from Kjeller, as the primary solution. Secondary, the committee recommended a further investigation of the possibility to establish an engineered rock cavity repository near Kjeller.

Based on this document a more detailed siting procedure was started in an area within a distance of 25 km from the waste conditioning facility at Kjeller. A systematic site screening process was carried out, in which 52 possible locations were identified and then reduced to 13 technically comparable sites. Further meetings with municipals and local authorities to discuss future land use plans and potential environmental impacts, reduced the alternatives to two sites (Kukollen, Himdalen) (4). An impact assessment was performed for these two sites and the closed Killingdal mine covering aspects such as area planning, industry, natural resources, historical sites, recreational areas and wildlife (2). A number of public meetings were held in potentially affected municipalities, and an official hearing was conducted.

After this procedure one of the sites, Himdalen, was recommended to the Government. The Government sent the recommendation to the Parliament where it was treated by the Energy and Environmental committee. The committee forwarded an adjusted proposal to the Parliament, in which the plutonium bearing waste, was suggested to be stored instead of being disposed of. It would then be possible to monitor and, if necessary, remove or recondition it at a later date. All short lived waste was to be disposed of. On 28 April 1994 the Parliament decided that the facility should be a combined storage and disposal facility and that the investigations at the Himdalen site should continue.

The builder and owner of the facility is the Directorate of Public Building and Property (Statsbygg). They build and own most of the public buildings in Norway. Statsbygg has to apply for a building license, make a detailed description of the building together with a safety report. According to the Atomic Energy Act, the Norwegian Radiation Protection Authority (NRPA) will review the safety report and provide advice to the Government on whether to give a license to start building of the combined storage and disposal facility.

IFE will be the operator of the facility. They will have to make a safety report for the operation and apply for an operating license. The Government will issue the license to the operator based on recommendations from the NRPA.

IAEA-WATRP REVIEW

NRPA requested an international peer review through the IAEA Waste Management Assessment and Technical Review Program (WATRP). The scope of the WATRP review is; the approach to the selection of site, the technical concept (combined storage/repository in a rock cavern), the long term safety. The members of the review team are from Switzerland (chairman), Canada, France, Germany and USA. The report of the WATRP review team was published in December 1995 (5). The main conclusions are that based on the existing information the team believes that the Himdalen site, in combination with the engineering concept, can be suitable for the storage and disposal of the relatively small amount of Norwegian LLW and ILW. Comments from this review will be taken into account when Statsbygg is finalizing the design and in the safety report. Comments will also be taken into account when the license application is treated.

DESCRIPTION OF THE COMBINED STORAGE AND DISPOSAL FACILITY

The combined storage and disposal facility will be built into a hillside in crystalline bedrock. The rock formation on the Himdalen site is Precambrian Mylonitised Gneiss.
The facility will have 4 caverns for the waste packages and one slightly declining 150 m long access tunnel for vehicles and persons. A service and control room, with certain crevice functions for the personnel, will be built along the tunnel and there will be a visitors room inside the facility. The layout is shown in Fig. 2. The rock caverns will be excavated with at least 50 meters of rock covering. The geological covering is for protection against intruders, plane crashes etc. and it is not intended to be taken into account as a barrier in the long term safety calculations.
Fig. 2
In the storage and disposal caverns, a granular base will first be installed as an underdrain for the facility, and a concrete floor will then be constructed on top of the granular base. Gaps will be left between the concrete floor and the walls of the caverns to allow ground water inflows to enter the underdrain.
Walls will be constructed on top of the concrete floor and the short lived waste packages will be stacked in 4 layers within the walls. At various stages the voids will be filled with concrete to create a solid sarcophagus incorporating the concrete floor and walls. The roof of the sarcophagus will be shaped to shed infiltrating ground water and a waterproof membrane will be fixed to the concrete roof. Void spaces will be left between the sarcophagus and the cavern walls and ceiling. This would create a hydraulic cage around the sarcophagus. Infiltrating ground water would tend to flow around the sarcophagus rather then through it. A similar construction is planned to be created for the plutonium bearing waste if it is decided in the year 2030 not to retrieve it.
There will be two separate drainage systems. a) All water entering the cavern shall be drained into a tank. This will be analyzed for radionuclides before it is released. b) One system of separate channels will be built under each cavern. This drainage system should always be dry. If water is detected here it has been in contact with the waste. It should then be possible to repair the damage, at least during operation. The facility will be designed taking seismic activity in the area into account (6).
Operation is planned to start in late 1996, the operational period is expected to last until the year 2030, this would take care of all Norwegian low and intermediate level waste, including decommissioning of the research reactors and laboratories at IFE.
Based on the experience during the operational period and safety reports for the closure, it will be decided whether to retrieve or dispose of the waste in the storage part by encasing it with concrete. During operation it is not intended to retrieve any of the waste that has been placed into the storage facility.
The facility will be closed by backfilling the disposal caverns in such a way as to permit functioning of the drainage for a very long time because it is anticipated that the caverns will be maintained in a drained condition after closure of the repository. After closure there will be an institutional control period of 300 -500 years with restrictions on land use and monitoring the discharges. Inspections or maintenance activities inside the underground excavations are not planned. Remedial actions

would be possible, if such actions appear to be necessary on the basis of the radionuclide content in the drainage waters.

THE LEGACY OF THREE MILE ISLAND, IMPLICATIONS FOR TODAY'S U.S. DEPARTMENT OF ENERGY CHALLENGES

Richard P. Coe
System and Industry Services
Michael S. Williams
William T. Conaway
GPU Nuclear Corporation

ABSTRACT

Over the course of the 16 year period following the accident at THREE MILE ISLAND - UNIT-2, much has been learned and volumes have been written regarding the cause and massive cleanup activities of the incident. Because of these "Lessons Learned", important changes have been made and the U.S. commercial nuclear industry is safer and more reliable as a result.

It is important to recognize that two major sources of information emerged from this event. First and foremost were the important safety issues that require immediate answers and the addition of the modifications to plants that these answers generated. Second and of considerable significance to the U.S. Department of Energy (U.S. DOE) in today's post-cold war environment are the frequently hard-won lessons involved with the recovery, clean-up, and defueling of TMI-2 and it's unprecedented transition into long-term, monitored storage.

While the production of nuclear weapons and the use of nuclear energy to produce electricity involve very different applications of nuclear technology, a comparison of the TMI-2 Recovery Project with the present DOE Weapons Complex activities identifies several strikingly similar challenges.

The cleanup of Three Mile Island, Unit-2 has been the most arduous and expensive program ever conducted by the U.S. commercial nuclear industry. Similarly, the defense weapons complex cleanup has been characterized as and is the most arduous program conducted by the DOE.

Perhaps the single most vexing area of similarity between the two projects is that, there was no one to turn to who faced a similar problem

set of such scope and magnitude. All ground was new ground. It is understood that the magnitude of the DOE situation is far greater then TMI-2 but the approach methodologies, programs and some of the resolutions can be directly applied to DOE activities. GPU Nuclear successfully managed the TMI-2 recovery program, is currently decommissioning its Saxton facility and is the successful operator of both a Pressurized Water Reactor (PWR) and a Boiling Water Reactor (BWR) commercial nuclear generating facilities. GPU Nuclear has maintained the capability to provide a complete computer based monitoring systems and simplify necessary systems to enhance safety for a long term storage configuration. This includes capability to evaluate the risks posed by the facility to workers and the public, while greatly reducing facility maintenance costs.

This GPUN experience is directly applicable to the massive DOE challenge for which long-term storage and monitoring of its facilities could be a cost effective alternative to costly decommissioning programs.

U.S. DOE/TMI-2 HISTORICAL PARALLELS

When reviewing the lessons learned from the TMI-2 Recovery Program, it is interesting to note the historical parallels which serve as a "common denominator" between the TMI-2 recovery and the DOE complex cleanup.

The U.S. DOE had a mission to produce nuclear weapons for the defense of the Nation and the Free World. The "Cold War" ended, the world changed and the mission was shifted from weapons production to facility stabilization and cleanup.

Three Mile Island, Unit-2 had a mission to generate electricity. The "Accident" occurred, the world changed and the mission was shifted from electricity production to facility stabilization and cleanup.

Both the U.S. DOE and TMI-2 were organized to efficiently fulfill the obligations of their respective missions. Virtually overnight, the missions of both organizations dramatically changed. With this shift came unique requirements and challenges which placed heavy demands on the existing organizational structures. Immediate requirements to stabilize facilities, protect worker and public health, develop new program plans and methods and do it with an immediate culture change have been thrust on both organizations.

The regulatory environment which governed the normal missions of U.S. DOE and TMI-2 was, in many cases, not well defined during unique time. This created a burdensome process of fitting existing rules and requirements into the context of the new mission objectives. In many cases it also meant the implementation of new regulations or rules. These were not only hard to learn and interpret but, in some cases, seemingly impossible to implement and still accomplish work.

SHARED CHALLENGES

While the production of nuclear weapons and the use of nuclear energy to produce electricity involve very different applications of nuclear technology, a comparison of the TMI-2 Recovery Project with the present DOE Weapons Complex activities identifies several strikingly similar challenges.

The cleanup of Three Mile Island, Unit-2 has been the most arduous and expensive program ever conducted by the U.S. commercial nuclear industry. Similarly, the defense weapons complex cleanup has been characterized as and is the most arduous program conducted by the DOE.

Perhaps the single most vexing area of similarity between the two projects is that there was no one to turn to who faced a similar problem

set of such scope and magnitude. All ground was new ground. It is understood that the magnitude of the DOE situation is far greater then TMI-2 but the approach methodologies, programs and some of the resolutions can be directly applied to DOE activities.

TMI-2 RECOVERY CHALLENGES

Decontamination and Dose-Reduction

The accident produced radiation and contamination levels that were unprecedented in the commercial nuclear industry. In the plant Auxiliary and Fuel Handling Buildings, radiation levels ranged from 50 to 5000 millirem per hour, with local "hot spots" up to 125,000 millirem per hour. Certain areas, such as the reactor coolant bleed tank rooms, contained radiation levels which exceeded 1,000,000 millirem per hour. Surface contamination levels, in some plant areas, ranged from 100,000 to 1,000,000 times greater than today's release limit standards. In every case, the Reactor Building radiological conditions were far worse. These harsh radiological conditions greatly exacerbated early plant stabilization and recovery operations because operator access to many plant areas was either extremely limited or denied altogether.

Due to the uniqueness and severity of the post-accident radiological conditions, GPUN developed a substantial degree of knowledge and skill with regard to large scale decontamination and dose-rate reduction activities. The following are highlights of the essential elements of this process:

A highly specialized and sophisticated Radiological Field Operations and Engineering Department was established in order to assure the health and safety of the work force and the public. This important function was essentially re-engineered from the ground up and the total work force exposure of less than 6500 person-rem, over the entire 16 year recovery period, is a testament to the success of the program.

The substantial utilization of remote technology was essential. This equipment was innovatively adapted to efficiently gather radiological and physical data from inaccessible plant locations, thus providing planners with vital information about plant conditions. Additionally, remote platforms were modified to accomplish the decontamination of these areas. The remote platforms literally saved thousands of person-rem.

The severe post-accident radiological conditions consisted of both very strong radiation fields and very high contamination levels. Effective remediation required the development of specialized equipment capable of "breaking down" the high radiation fields into several contributor sources. The more severe radiation levels were eliminated first. This type of equipment was particularly useful during system flushing because radiation levels could be monitored in real time and excessive flushing operations could be avoided.

Decontamination and dose-rate reduction activities are not series events. They had to be accomplished in a defined pattern in order to achieve optimum and lasting results. Considerations such as personnel safety, waste form, waste minimization, ventilation flow patterns, occupancy requirements, impact on adjacent areas, fire prevention, etc., played an important role in the planning and execution of this type of activity.

Due to the presence of high surface contamination levels and widely distributed high-energy beta radiation fields, work force personnel conducted their activities in a substantial array of protective clothing. While this clothing provided protection from contamination and beta

radiation, it also produced high levels of "Heat Stress" and dramatically reduced the amount of time that workers could safely remain in the work areas. To overcome this problem, the project team pioneered the development of an extremely effective and efficient "Heat Stress Control Program". The program and its supporting equipment provided the capability to significantly extend worker stay time and work efficiency while reducing heat stress, radwaste and radiation exposures.

All work in the TMI-2 Reactor Building involved the potential to interface with very high radiation fields. In order to accomplish efficient work in this environment, a "Command Center" system was developed. Using this system, the Reactor Building work force personnel were constantly monitored via closed-circuit video equipment and two-way radio communications. Supervisors, managers, safety & health specialists and radiological control personnel were able to constantly monitor workers and provide instantaneous resolution to questions and problems. This system was extremely effective in monitoring work and minimized worker exposures to both radiological and industrial safety hazards.

The capability to expeditiously and effectively get personnel into and out of, harsh radiological areas was essential. During the TMI-2 recovery, GPUN developed and implemented a highly specialized work center which was responsible for preparing personnel for entry into the Reactor Building, providing logistical support for entry teams and assisting in personnel egress. This work center, in close cooperation with the "Command Center", significantly enhanced the safety and efficiency of operations. At the same time, it greatly minimized worker contaminations, increased organization to contaminated laundry collection, radwaste collection and controlled the spread of contamination and hot particles. This method is still in use in other GPUN plants.

RADIOACTIVE WATER CLEANUP

The accident initially produced hundreds of thousands of gallons of contaminated water. The ensuing recovery and decontamination programs produced millions of gallons of highly contaminated water. All this created several , large-scale and difficult radioactive water clean-up challenges. The project team developed and implemented numerous, highly specialized, water processing systems which were successfully utilized to safely clean-up and dispose of all radioactive water resulting from the accident.

The accident-generated radioactive water varied considerably depending on its source, transportation path, final storage location and dilution factors. Reactor coolant samples obtained on the day of the accident were in the milli-curie per milli-liter range. Water in the Auxiliary Building sumps and tanks was generally below 100 micro-curies per milli-liter while water from the Reactor Building exceeded that figure.

A number of focused radioactive water processing campaigns were conducted in order to satisfy recovery program objectives. These campaigns included the following:

Processing of the Auxiliary Building water inventory.

Processing of the Reactor Building Basement water inventory.

Processing of the highly contaminated Reactor Coolant water inventory.

On-going processing of "Previously Processed" water which was continually recycled in support of decontamination operations.o On-going processing of Reactor Coolant water to maintain water clarity during defueling operations. Maintaining water clarity for defueling operations became incredibly complex due to very small fuel debris and the

proliferation of organic materials which became established in the reactor coolant system. Methods of organic control debris removal were developed and successfully utilized.

Specialized programs were developed for processing contaminated resins and sludge effluents from plant demineralizers and sludge removal operations from sumps and tanks.

Final processing and evaporization of all accident-generated water was 2.3 million gallons of water from TMI-2.

Full and complete training in all aspects of system operation were developed and implemented. Training was also included in all aspects of expected system performance and radiological concerns.

RADIOACTIVE WASTE MANAGEMENT

The TMI-2 accident created enormous quantities of widely varying radioactive waste forms which were well outside the normal capabilities of a commercial nuclear power plant. This waste generally resulted from water cleanup operations, decontamination and dose reduction activities and defueling. As a result of the accident, the project team developed substantial expertise involving all aspects of waste management. GPUN found that the following elements were crucial in the safe and proper control and minimization of radwastes:

Waste Characterization - Radwaste characteristics can vary substantially even though the waste originates from the same general area or was caused by a similar process. A complete understanding of the radiological and chemical constituents, as well as the physical processes and regulatory requirements, essential in developing the simplest organized approach. Analysis of huge banks of data was then formatted to support efficient processing, packaging, and disposal procedures and methodologies.

Process Control Program - The Process Control Program varied from a single document to a collection of many documents which provide the basic procedures for determining cleanup processes, methodologies, and specific end point or acceptance criteria. The Process Control Program was essential to the operation of a processing system so that optimum performance is achieved while assuring overall program goals were met. Well structured, simple procedures were essential to support the safe and reliable performance of a system and the proper handling of the resultant waste.

Training - The best equipment and procedures were of limited value if the workforce did not comprehend their significance and recognize the importance of compliance. Because of the variety of waste forms resulting from the accident, it was imperative that each and every member of the team receive a full and complete understanding of the waste streams within the plant and the programmatic and safety significance associated with proper handling and control. A series of specialized training programs were developed. To reinforce the importance of the training, sessions were attended by, and frequently presented by, senior management responsible for the different project teams.

Chemical Control - TMI-2 instituted an extensive chemical control program in order to prevent cross-contamination of radiological wastes with chemical wastes. This was again supported by meaningful training programs.

Packaging & Handling Radwaste Containers - The project team developed substantial experience in the safe and proper packaging, handling, storage, and shipment of hundreds of highly radioactive waste containers.

This also required the requisite knowledge of regulatory requirements and the interpretive ability to specify whether lease, purchase or construction of containers would meet the regulatory requirements for transportation and disposal.

Waste Container Radioactivity Content Estimation and Prediction - Highly restrictive state and federal transportation and burial regulations dictate strict limitations on radioactive material content within waste containers destined for disposal. It was equally important that radioactive material loading within process containers be maximized to achieve the greatest economy. This apparent dichotomy required the ability to accurately predict the amount for radioactivity within a container during loading operations. The production, shipment, and disposal of several hundred containers was successfully accomplished.

Explosive Gas Generation Determination - The energy deposition from radiation interacting with hydrogenous material can cause the liberation of hydrogen gas. This process can create potentially explosive concentrations of hydrogen gas within sealed waste containers. Federal transportation regulations prohibit the shipment of this type of explosive mixture. Proper processing controls, container selection, handling, preparation for shipment and prediction of gas concentrations were required to mitigate potentially dangerous situations.

Waste Disposition - Simply put, the TMI-2 goal was to find the best method for waste removal. Each specific waste type was evaluated and prepared for disposal after considering regulatory requirements, scrap value, processing and disposal costs. Construction of an "On-Site" Waste Handling and Packaging Facility with all of the associated controls and staffing costs was determined to be a cost effective investment. The facility paid back its construction and operating costs over a very short period of time.

Throughout the entire recovery process there were several notable and unique examples of radioactive waste handling, packaging, and shipment.

Underwater Loading of Shipping Casks - A special underwater processing system was constructed and placed into operation. The excellent shielding provided by this configuration permitted extremely high levels of radioactive materials to be captured by the system process vessels. The resultant cleanup vessel radiation levels were dangerously high (the highest loaded vessel contained approximately 158,000 curies). Methods and techniques were developed to load the processing vessels into a heavily shielded shipping cask under water. This unprecedented process was safely conducted throughout the operating cycle.

Specialized Transloading Shipment to Disposal - Disposal of several processing vessels required confinement in a specialized disposal container. Facilities to allow radiologically safe conduct of this process were not available at TMI-2. Working with a national laboratory, GPUN coordinated and directed shipment of 14 highly radioactive vessels to the laboratory facility. These vessels were then transloaded into the GPUN special disposal containers and shipped. This operation was unique to both the national laboratory system and the commercial industry.

TMI-2 Fuel Debris Shipment - During the defueling phase of recovery, the severely damaged fuel was placed into specially designed containers for shipment and storage. Due to the damaged nature of the fuel, a new generation of shipping cask had to be used to ship the fuel safely. This task required close interface between DOE, NRC, and GPUN in order to

successfully design, license, fabricate, test and operate a new generation cask.

TMI-2 DEFUELING

The most technically challenging aspect of the TMI-2 recovery program was the removal of the 100 plus ton volume of damaged fuel from the Reactor Vessel. Many concepts were considered to perform this operation most of which required considerable development. The developmental nature of otherwise attractive proposals raised many substantial questions and concerns. This led GPUN to develop a defueling concept which utilized operators on a rotating work platform above the Reactor Vessel using long-handled tools and underwater cameras, to accomplish the defueling operations. This approach also allowed for rapid solutions to unexpected problems without having to make extensive modifications to elaborate systems.

A full scale mock-up of the TMI-2 Reactor Vessel internals provided defueling team personnel with an excellent facility for training and tool/method evaluation. By training and refining techniques and equipment, enormous radiation exposure savings were realized. Additionally, this approach allowed the development of incremental improvements in tool design as operators became more familiar with the tools and could make suggestions for enhancements.

The fuel removal operation could best be characterized as "one gigantic technical hurdle after another". No sooner would the team solve a particularly vexing problem then the next one showed up. One central theme rang clear, "Keep it Simple". Generally, the less complicated the approach, the better. The following involved simple solutions to difficult problems:

Following completion of the removal of the loose debris which covered the top of the post-accident core, a very large, hard mass of resolidified core was exposed. This material proved impervious to the long handled tools developed to break it apart. A small commercial drilling rig that had been originally used to take bore samples of the damaged core was fitted with a solid-faced bit, allowing the team to break up the resolidified mass by drilling approximately 400 holes into the core mass. This process, which came to be called "Swiss Cheesing", was very effective.

Removal of small pieces of core debris was a problem. The original vacuum system did not operate satisfactorily. An air lift system (suction dredge) was fabricated and employed to perform vacuuming operations. This simple system was responsible for the most productive months of defueling during the entire cleanup program.

GPUN also designed a family of specialized canisters into which the damaged core debris was placed for storage and shipment. These canisters were able to accommodate the full range of core conditions, from intact assemblies to chunks, to extremely finely divided particles which resulted from the destructive defueling methods.

GPUN had extensive pre-accident experience in handling new and spent low enrichment nuclear fuel. This experience along with the DOE experience and others led the group to decide that canisters and a new generation shipping cask were required to safely ship the core.

GPUN loaded the specialized canisters with core material then loaded the canisters into the DOE owned shipping cask. GPUN then prepared the cask documentation and the fuel was shipped to the Test Area North (TAN) facility at INEL for R&D, storage, and eventual disposal.

The core was shipped in 342 canisters in 49 cask loads requiring 22 trains - all without any regulatory violations or major incidents over the four year defueling period.

POST-DEFUELING MONITORED STORAGE

With the recovery program of TMI-2 complete and successful, GPU Nuclear has since moved this facility to long-term monitored storage.

A remote monitoring system allows the owner to detect changes in facility conditions, particularly those that can lead to unsafe conditions for workers or the public. Since the TMI-2 nuclear plant was to be placed in a long-term monitored storage condition, installing such a system was important to minimizing facility costs.

GPU Nuclear successfully managed the TMI-2 recovery program, is currently decommissioning its Saxton facility and is the successful operator of a Pressurized Water Reactor (PWR) and a Boiling Water Reactor (BWR) commercial nuclear generating facility. GPUN has maintained the capability to provide a complete computer-based monitoring system and simplify necessary systems to enhance safety for a long-term storage configuration. This includes capability to evaluate the risks posed by the facility to workers and the public.

This GPUN experience is directly applicable to other industrial or laboratory situations for which long-term storage and monitoring of the facility is required or could be a cost effective alternative to costly decommissioning programs.

SPENT FUEL MANAGEMENT AT NORTHERN STATES POWER COMPANY

John Closs
Nuclear Consultant

Lon Kress
Northern States Power Company
Engineering Intern
414 Nicollet Mall
Minneapolis, Minnesota 55401

ABSTRACT

The Northern States Power Company (NSP) has developed an extensive spent fuel management program to resolve storage limitations at the NSP nuclear plants. Amidst great political opposition and legal restraint, the program has successfully provided for the continuation of nuclear power at NSP.

INTRODUCTION

The disposal of nuclear waste has become a critical factor in the continued operation of several commercial nuclear power plants in the United States. Disputes over federal responsibility in accepting spent nuclear fuel have forced some utilities, including NSP, to seek interim storage solutions. As the litigation over storage and disposal alternatives wages on, spent fuel pools continue to fill and plants edge closer to premature shutdown.

This paper discusses the spent fuel management program at NSP, including the Independent Spent Fuel Storage Installation (ISFSI) project at the Prairie Island Nuclear Plant. It provides a historical overview of the program, discusses recent developments, and concludes with a prospectus of NSP plans for resolving the nuclear waste dilemma.

NSP Spent Fuel Management Program

NSP owns and operates two nuclear power plants: Monticello, a single unit boiling water reactor (BWR), and Prairie Island, a dual unit pressurized water reactor (PWR). Like many reactors built in the 1960s and 1970s, the NSP units were designed for limited and temporary spent fuel storage, with the expectation the fuel would later be removed and reprocessed. In 1977, a federal moratorium against reprocessing forced utilities to retain spent fuel at the plants. To accommodate the additional storage requirements, NSP attempted to increase the storage capacity of the spent fuel pools through fuel consolidation and redesign of the holding racks. The enhancements, however, were insufficient to allow the accumulation of fuel for an extended period of time.

The Monticello nuclear plant does not currently present a spent fuel storage problem. During the initial cycles of operation, fuel bundles were leased from the General Electric Company (GE). The spent fuel bundles were temporarily stored in the plant holding pool until storage capacity became scarce, at which point the fuel was returned to GE. In all later cycles, GE sold fuel bundles directly to NSP, which assumed responsibility for the storage and disposal of the spent fuel.

At Prairie Island, storage capacity was nearly exhausted, despite reracking the spent fuel pool twice. The redesigned storage pool, shared between the two units, could not support operating cycles beyond 1995. To sustain plant operations, NSP initiated a highly controversial effort to obtain approval for an ISFSI, a temporary onsite dry cask storage facility.

ISFSI Project

In the early 1980's, NSP anticipated a fuel storage dilemma and began evaluating options. In May, 1989, NSP announced its decision to temporarily store spent fuel in dry storage casks. The announcement initiated a long and exhaustive review process (Table I). After unanimous approval from the Public Utilities Commission (PUC) and the Nuclear Regulatory Commission (NRC), the construction of the ISFSI site began in September, 1992.

In June, 1993, court appeals by opponent groups forced a suspension of the preparatory work on the ISFSI site. At that time, the on-site construction was essentially complete and the production of the casks was progressing successfully. The Minnesota Court of Appeals determined the duration of storage would be in excess of eight years, which it ruled as permanent storage. Because Minnesota statute requires legislative approval for "permanent" high level and low level waste sites, further progress on the project required approval by the Minnesota Legislature.

In January, 1994, NSP submitted testimony before a number of Minnesota House and Senate committees requesting the legislature's ratification of the spent fuel storage facility at Prairie Island. Representatives attested to the safety of the ISFSI technology and the necessity of the facility in providing for the electrical, economic, and environmental needs of the communities serviced by NSP.

Minnesota Legislation Results

On May 6, 1994, the Minnesota Legislature enacted bill S.F. No. 1706: "relating to public utilities; providing legislative authorization of the construction of a facility for the temporary dry cask storage of spent nuclear fuel at Prairie Island nuclear generating plant; providing conditions for any future expansion of storage capacity; approving the continued operation of pool storage at Monticello and Prairie Island

nuclear generating plants; requiring development of wind power; regulating nuclear power plants; requiring increased conservation investments; providing low-income discounted electric rates; regulating certain advertising expenses related to nuclear power; creating a legislative electric energy task force; appropriating money; ..."

In essence, the bill provided for the continued operation of the NSP nuclear plants in the near term. However, it set forth the eventual abandonment of nuclear power in the state of Minnesota through mandates on alternative energy sources, economic regulations, and miscellaneous rate ordinances.

A total of 17 Transnuclear TN-40 storage casks, of the original 48 requested, were authorized for Prairie Island. The casks will be dispensed to the site in three intervals pending NSP's compliance with the legislative mandates. The elements of the bill regarding dry cask authorization are:

1. Five casks are authorized for immediate use.
2. Four more casks will be authorized if, by December 31, 1996:
   NSP has filed a license application with the NRC for an alternate ISFSI site off of Prairie Island in Goodhue County.
   NSP continues to make a good faith effort to implement the alternate site.
   NSP has constructed, contracted for construction and operation, or purchased an additional installed capacity of 100 MWe of generation from windpower.
3. Final eight casks will be authorized if, by December 31, 1998:
   NSP has constructed and operates, purchased, or contracted to construct and operate a total additional installed capacity of 225 MWe of generation from windpower.
   NSP has constructed and operates, purchased, or contracted to construct and operate an additional installed capacity of 50 MWe of generation from farm grown closed-loop biomass.
   An alternative ISFSI site in Goodhue County, Minnesota, is operational or under construction.

If NSP fails to satisfy the mandates for December 31, 1998, the Minnesota Legislature may revoke the authorization for the final eight casks, if a law ordering the revocation is enacted before June 1, 1999.

The bill also specifies that NSP and the Governor, acting on behalf of the state of Minnesota, must reach a contractual agreement on the cask plan. The provisions of the contract, as later established in the Energy Policy and Storage of Spent Nuclear Fuel Act, include:

1. Considerations for the siting of an alternative ISFSI site.
2. Additional renewable energy alternative requirements to be implemented, without regard to cost, by December 31, 2002:
   NSP must construct and operate, purchase, or contract to construct and operate a total additional installed capacity of 425 MWe of generation from windpower.
   NSP must construct and operate, purchase, or contract to construct and operate a total additional installed capacity of 125 MWe of generation from farm grown closed-loop biomass.
3. Designation of the Mdewakanton Tribal Council as the third-party beneficiary of the contract, with standing to enforce the agreement.

The legislative act further mandates:

4. Additional renewable energy alternative requirement to be implemented, under the resource planning process, by December 31, 2004:

NSP must utilize 400 MWe, in addition to the required 425 MWe, of generation from windpower if the energy need exists and the cost of windpower is the same or lower than non-renewable alternatives.

A large emphasis has been placed on the "temporary" designation of the casks. The spent fuel stored in the casks must be moved to an alternative storage site as soon as a site becomes available. For any casks remaining at Prairie Island after January 1, 1999, NSP must transfer $500,000 per cask, per year to a "Renewable Development" account.

In addition to the cask limitations, NSP must accept certain responsibilities for the newly established Legislative Electric Energy Task Force, assigned to study and make recommendations on future energy options. The bill specifies that NSP must provide:

1. "Dry Cask Alternatives Study" reevaluating alternative combinations to dry cask storage.
2. "Worker Transition Plan", issued to the Department of Jobs and Training, in the event the Prairie Island nuclear generating station is shutdown for more than six months.
3. "Nuclear Power Phase-out Plan" for the entire NSP nuclear generation sector.
4. "Decommissioning Plan" for the TN-40 casks once they are emptied of spent fuel.

Though the Minnesota Legislature has not ordered the immediate closure of operating nuclear plants, nuclear power will be under close scrutiny in the state of Minnesota. Except to accommodate the decommissioning of a nuclear power plant, the current storage capacity for high-level nuclear waste will not be increased. The construction of a new nuclear-powered electric generating station is strictly prohibited. The bill also states that any nuclear reactor unit which has an annual capacity factor of less than 55% for three consecutive years will be required to shut down and cease operations.

Status of NSP Compliance

Wind:

In accordance with the first legislative mandate for December 31, 1996, NSP must acquire an additional installed capacity of 100 MWe of generation from windpower produced within the state. NSP intends to develop a wind energy conversion system to accommodate this requirement. A Certificate of Need (CON), issued by the PUC, and a siting certificate, issued by the Environmental Quality Board (EQB), were filed in late September, 1994. NSP has issued a Request for Proposal (RFP) and is evaluating bids.

The wind conversion system will be implemented in phases. Phase 1, which has been completed, involved a contract for an existing 25 MWe from the Kenetech Company, which owns and operates 73 wind turbines in Lake Benton, Minnesota. Phase 2 entails the development of a 100 MWe plant, which has been contracted to Zond Systems Incorporated. Phase 3 will include an additional 100 MWe plant, for which the CON is currently before the PUC. The EQB will manage the siting of windpower plants and develop Environmental Impact Statements (EIS). After public review, the EQB will designate sites.

Alternative Site:

Another requirement of the first legislative mandate is Nsp must file a comprehensive license application with the NRC for an alternate ISFSI site in Goodhue County, Minnesota, and make a "good faith" effort to

implement the site. For the initial identification and evaluation process, NSP assembled a Public Advisory Committee (PAC) to serve as a liaison and represent diverse interest groups in the county. With the assistance of the Stone & Webster Engineering Corporation, NSP has identified two candidate sites in southeastern Goodhue County and has filed a Site Certificate Application to the EQB for further consideration. The EQB has begun an extensive siting process while NSP assembles information required for an NRC license. The application documents will be submitted to the NRC in 1996. Pending public intervention, the review process can require up to three years to complete.

Biomass:

In accordance with the second legislative mandate for December 31, 1998, NSP must acquire an additional installed capacity of 50 MWe of generation from farm grown closed-loop biomass. NSP has submitted an RFP to the PUC. An independent evaluator is evaluating bids and will make a recommendation to NSP.

RECENT DEVELOPMENTS

ISFSI Site Implementation

On May 23, 1995, NSP placed the first loaded TN-40 dry storage cask on the Prairie Island ISFSI site, which allowed a refueling outage of Unit 2 to proceed as scheduled. The second and third casks have also been loaded and placed on the holding pads to allow for refueling of both units. The remaining two authorized casks will be delivered to the plant at monthly increments. Each cask is meticulously inspected upon arrival then immediately loaded and placed inside the heavily secured facility.

Utility Lawsuit

A group of 14 utilities, led by NSP, are pursuing a lawsuit against the U.S. Department of Energy (DOE). The suit was filed on June 20, 1994, in the U.S. Court of Appeals in an attempt to clarify the DOE's obligation regarding spent nuclear fuel. NSP is joined by several other utilities, public agencies, and state governments nationwide which believe the federal government has a contractual responsibility to accept commercial spent nuclear fuel beginning in 1998. The lawsuit has been admitted for judicial hearing and awaits final resolution.

Private Spent Fuel Storage Initiative

On March 9, 1995, the Mescelaro Apache Tribe passed a referendum to establish a temporary storage facility on the Mescelaro Reservation in New Mexico. A consortium of utilities and contractors have committed to developing a privately operated spent fuel storage facility for interim use until a federal repository becomes available. In addition to providing a temporary solution to the spent fuel storage dilemma, the facility would contribute to the self-sufficiency and economic diversity of the Tribe and the surrounding communities. Development of the Mescelaro facility would not relieve the federal government of its obligation to begin taking fuel from utilities in 1998.

In the near term, NSP will still require all 17 allotted dry storage casks at Prairie Island in order to maintain continued operation of the plant. Even if the interim storage project is successful, a storage facility in New Mexico would not be available until 2002. A permanent underground repository, under study at Yucca Mountain, Nevada, is not expected to be ready until 2010 at the earliest.

Dry Fuel Storage Conference

On July 25, 1995, NSP, in coordination with the Nuclear Energy Institute (NEI), hosted a industry workshop on dry fuel storage. Representatives from nearly two dozen utilities attended the forum to discuss and resolve problems observed in utility dry fuel storage projects.

The predominant issue discussed was inadequate quality assurance in the manufacturing and procurement of storage containers. Industry experience has demonstrated the process is remarkably complicated and susceptible to poor oversight. Additional concerns involved project licensing and field loading of the casks.

As a result of the NSP/NEI conference, the industry can better prepare for the challenges of dry fuel storage. The knowledge gained by the utilities and regulators may allow for improved management of spent nuclear fuel, increasing safety while decreasing costs.

NSP PROJECTED PLANS

The primary objective for the NSP spent fuel management program will be ensuring the uninterrupted operation of the nuclear power plants, particularly Prairie Island. Of immediate concern will be the implementation of the remaining two dry storage casks to provide for the next refueling outage. Prior to utilizing the casks, NSP is required to perform a substantial amount of training, rehearsal, and system checks in accordance with the NRC license for the ISFSI.

To prepare for future refueling outages, NSP will continue to implement the legislative mandates which provide for additional storage casks at Prairie Island. The next deadline of December 31, 1996, requires that NSP makes progress in establishing an alternate ISFSI site in the Goodhue County and installs an additional capacity of 100 MWe of generation from windpower. Plans to meet these requirements have been initiated and are progressing on schedule.

NSP will maintain close liaison with the DOE to accept spent fuel in 1998. There are a large number of utilities nationwide which produce a significant portion of their power from nuclear reactors. Many of these reactors, such as Prairie Island, were designed for only limited and temporary storage of spent nuclear fuel. The federal government accepted responsibility for the removal and disposal of spent fuel. In compensation, it collected funds, totaling over $11 billion, from the utilities and their customers. The Department of Energy, under the direction of Congress, has a moral and legal obligation to the utilities to uphold its commitment.

CONCLUSIONS

In a determined effort to obtain political and public acceptance of an ISFSI at the Prairie Island nuclear plant, NSP has developed an extensive and successful spent fuel management program. The program has revealed some of the areas of contention and concession in approving on-site dry cask storage, which may prove beneficial to other utilities requiring interim storage solutions. To provide for the continuation of nuclear power, NSP will persist in seeking solutions to the nuclear waste dilemma.

STATUS OF MULTI-PURPOSE CANISTER (MPC) PROJECT

J. Pat Hopper
Scientific Ecology Group, Inc.
Westinghouse Government and Environmental Services Company

ABSTRACT

The Multi-Purpose Canister (MPC) project represents a cornerstone of the current DOE Office of Civilian Radioactive Waste Management (OCRWM) program for handling spent nuclear fuel. The MPC and associated support equipment is being designed to accommodate the requirements for not only storage and transport but also for the specified disposal requirements of the Mined Geologic Repository System. The Phase 1 design effort for the MPC system, being performed by the Westinghouse Team on behalf of the OCRWM Management & Operating (M&O), is on schedule for delivery of completed Safety Analysis Reports (SARs) in April 1996.

INTRODUCTION

This paper addresses the current status of the Multi-Purpose Canister (MPC) Project. The MPC Project was awarded to Westinghouse by TRW Environmental Safety Systems, Inc. (TESS) on behalf of the Department of Energy. TESS is the Management and Operating Contractor (M&O) for the DOE Office of Civilian Radioactive Waste Management (OCRWM). Westinghouse, as the lead subcontractor, is performing the design, licensing, testing and fabrication of a complete storage, transport and disposal system for handling spent nuclear fuel in a three phase program. The MPC Project represents a cornerstone of the current OCRWM program for handling spent nuclear fuel. The MPC, in conjunction with the Mined Geologic Repository System, represents the solution to the nation's spent fuel disposal dilemma.

The status of the design, Safety Analysis Report submittal to the NRC, preparations for fabrication of prototypes and out year plans are discussed.

BACKGROUND

The U.S. Department of Energy recognized the importance of dry spent nuclear fuel storage and took a critical step toward addressing this need by awarding the MPC contract in April 1995.

The Westinghouse Team includes Packaging Technology, Inc. of Tacoma, Washington, Chem-Nuclear Systems, Inc. of Columbia, South Carolina, Westinghouse divisions in California, New Mexico, Tennessee, and Pennsylvania and E.J. Bentz and Associates in Springfield, Virginia. Select domestic utilities are also supporting the Phase 1 system design and development as utility advisors to the design team.

The design activity and Safety Analysis Reports (SARs) will be complete by 26 April 1996, marking the conclusion of Phase 1 of the program. Phase 2 consists of the USNRC certification process for the 10 CFR 71 and 10 CFR 72 licensed components of the MPC System, associated testing and the fabrication of prototype hardware for system level demonstration and ultimate qualification of the MPC system for use by utilities and site operations. Phase 3 consists of the fabrication and delivery of the initial complement of approximately 150 Multi-Purpose Canisters and automatic welding/drying equipment. Both Phase 2 and 3 are contract options to be exercised as appropriate by the M&O.

Additionally, key reports and studies have been accomplished and submitted to TESS as required. These include the System Safety Report, Human Factors Engineering Report, Critical Operating Times (COT) and Reliability, Availability and Maintainability (RAM) Report, MPC System/Bare Spent Nuclear Fuel Transfer (BST) Interface Report, SAR Alternative-Enhanced Fuel Study, SAR Alternative-Stainless Steel Fuel Clad SNF Study, and the Depleted Uranium Shield Plug Study. Meetings with the utility advisors have provided valuable feedback used to influence these studies and the overall design process, from the ultimate users

standpoint, leading to the Preliminary Design Reports (PDRs) and Safety Analysis Reports (SARs).

MPC SYSTEM DESCRIPTIONS

The MPC system is being designed per requirements set forth in specifications provided by the M&O to contain SNF from commercial boiling water and pressurized water reactors (BWR, PWR respectively). The overall MPC system design concept is shown in Fig. 1. The MPC is designed in two (2) sizes: 125 ton and 75 ton. Because of the weight, the MPC is intended for rail shipment, however, in cases where the nuclear power plant or a potential interim storage site lacks rail access, the casks and system components are to include heavy haul means.

Fig. 1

The MPC has been designed incorporating highly corrosive resistant materials. Inside the canister is a metal frame or "basket" that has three functions: 1) structural support and criticality control for the SNF assemblies, 2) transfer of heat from the SNF to the canister walls, and 3) maintenance of the fuel in a totally safe condition during any normal, and postulated accident scenarios. Once loaded with spent fuel assemblies, the MPC will be permanently sealed by automatic welding, dried and backfilled with an inert atmosphere and then loaded into a cask for each phase of storage (whether it be at a nuclear power plant or interim storage facility), transport and disposal. Other MPC system elements that will be developed include an On-site transfer and Storage System for loading and on-site storage of MPCs, and for transferring MPCs into transport casks for MPC transport to interim storage or disposal sites.

MPCs are being designed with broad fuel acceptance parameters to accommodate all PWR and BWR assembly types and classes, specifically all Zircalloy clad fuels (except South Texas and CE 16x16 with control components). Stainless steel clad fuels can physically be accommodated by the design. The MPC design essentially handles all of the fuel in the projected inventory.

CURRENT PROJECT STATUS

Approach

The initial effort on the MPC project involved the preparation of the basic program guidance documents. These prescriptive documents (see Fig. 2) were submitted to and approved by TESS and form the basis for managing the Project.

Fig. 2

The Phase 1 MPC system design process was structured in a three step approach 1) concept optimization, 2) detailed design, and 3) SAR preparation. Concept optimization was scheduled for the first three (3) months of the project and consists of establishing the baseline configuration for an integrated MPC system. Once the baseline configuration was fixed, the second step was to complete the detailed calculations, perform thermal, shielding and structural analyses and prepare the design drawings required to fully define and specify the components. The final stage is to prepare the Preliminary Design Reports (PDRs) and SAR chapters in preparation for submittal of the SARs for USNRC certification review.

The concept optimization was completed on schedule and culminated in a two day formal Design Concept Review (DCR) and technical exchange. The DCR was attended by the DOE, the M&O and a number of utility advisors.

Feedback and comments from the DCR were factored into the baseline design process during the detailed preliminary design.

The key driver for the MPC system integrated design is the basket configuration and source terms. The four basic basket designs (12 assembly PWR, 21 assembly PWR, 24 assembly BWR and 44 assembly BWR) have been completed and are illustrated in Table I. Structural, thermal, criticality and shielding analyses are underway to facilitate the final detailed design of the remaining system components.

Table I

All the designs are based on the Design Procurement Specifications (DPSs) issued by the M&O, Based on the primary design parameters given in the DPSs, an MPC Functional Specification was prepared and issued for design team use. The MPC Functional Specification provides the extrapolation of the DPS to a system level design basis and provides additional guidance to the designers. For example, the MPC Functional Specification allocates weight parameters between system level components. System Specification Documents (SSD's) were then prepared to define the detailed specifications applicable to each configuration item being designed (see Fig. 3). All SSDs have been completed as well as the interfacing control points for each piece of hardware. Hardware interfaces are defined and controlled using an Interface Control Sheet mutually generated by each involved design agency and approved by the Chief Design Engineer.

Fig. 3

One unique feature of the Westinghouse Team design effort is the "concurrent engineering" approach being utilized. Concurrent engineering has been successfully used to integrate the disciplines of manufacturing engineering with the design engineering to enhance component fabricability and perform value engineering. This integration was implemented at the beginning of the project, has resulted in very active interchanges among the design team and prospective material suppliers, and has resulted in a design that can be built cost effectively. Design options are discussed with the fabricators to generate the most cost effective project and to help ensure a smooth transition from design drawing to the shop floor. Additionally, the goal is to maximize the use of standard processes and tooling, further reducing the cost to produce MPCs.

The MPC design process has also taken the approach to utilize many previously NRC accepted materials, analytical methods, acceptance criteria, etc., to maximize the potential for successful licensing of the Part 71 and 72 components. Four meetings have been held with the NRC to discuss the MPC design details and approaches as well as potential certification issues that have surfaced during the design process. This proactive approach has been beneficial in the timely resolution and selection of design options that have the best chance to be licensed within the constraints of the program schedule; i.e., deployment of the MPC by 1998.

The Preliminary Design Reports (PDRs) are segregated into three phases. The first PDR grouping covering auxiliary equipment has been completed and submitted to TESS. The remaining two (2) PDRs covering the storage unit and the MPC assemblies will be completed in the Spring of 1996 to complete Phase 1 of the project.

QUALITY ASSURANCE

All hardware items requiring USNRC certification under 10 CFR Part 71 and 10 CFR Part 72 are being designed by teammates with USNRC approved

quality assurance programs. The suitability of each teammates' QA program was determined at the beginning of the contract. QA audits and surveillances (internal, by the M&O and by OCRWM) have been conducted frequently throughout the performance of the design effort and compliance with QA requirements has been achieved. Corrective actions have been initiated promptly as required.

A Quality Items List (Q-List) has been generated as a part of the Phase 1 design effort. Each hardware configuration item was categorized according to NRC guidelines to designate items required for protection of public health and safety and for occupational radiological exposure control.

PHASE 2 AND PHASE 3 FORECAST

Phase 2 consists of the USNRC certification process for the MPC System, associated testing and the fabrication of a number of prototype hardware items. Phase 3 consists of the fabrication and delivery of the initial complement of approximately 150 Multi-Purpose Canisters and welding equipment. Both Phase 2 and 3 are contract options to be exercised as appropriate by the M&O.

In the Fall of 1995, after OCRWM took action to reduce the activity in the OCRWM program from the FY95 level of $512 M to $400 M, consistent with the continuing resolution, Congress appropriate $400 M for the program and reserved $85 M from use pending enactment of separate legislation. The level of funding available to the program is $315 M, which required further reductions in activity. Phase 1 will be completed, but the work scope has been reduced to eliminate activities in preparation for the second and third phases. Therefore, funding for Phase 2 and 3 is postponed until an authorization bill is passed. The program does not anticipate proceeding to the next phase, consisting of NRC certification and prototype fabrication, or to the third phase of MPC fabrication and deployment beginning in 1998.

SUMMARY

The Westinghouse MPC program is proceeding on schedule for the design of MPC system components and submittal of the SARs on 26 April 1996. Due to funding constraints placed on the program by Congress, OCRWM has chosen not to exercise the Phase 2 MPC certification and prototype fabrication option as originally planned, pending legislative actions that would free up the $85 M of funds set aside late last year.

As Ivan Selin, Chairman of the NRC, has stated in testimony before the Senate Committee on Energy and Natural Resources, the Multi-Purpose Canister represents the only way to link all phases of spent fuel handling (that is storage, transportation and disposal) in one integrated approach. We believe the MPC maximizes the degree of standardization in equipment and infrastructure needed to operate a cost-effective OCRWMS and reduces the degree of specialized equipment, etc., that would be required to handle SNF if the MPC system were not the baseline.

The DOE and the NRC have recognized that utility customers deserve a cost-effective, integrated and standardized system for the billions of dollars they have contributed under the Nuclear Waste Policy Act to support the management of civilian radioactive waste. Spent nuclear fuel needs to be managed safely, cost-effectively and within the best technology available. The MPC represents both a critical first step, and long-term standardized solution to the way this nation should approach the issue of spent nuclear fuel management.

RECYCLING OF LOW-LEVEL RADIOACTIVE ION EXCHANGE RESINS: A CASE STUDY

Jeff Bramblett
Mark Kirshe
Chem-Nuclear Systems, Inc.
140 Stoneridge Dr.
Columbia, SC 29210

ABSTRACT

In the past, ion exchange resins used to clean up radioactive process fluids have been disposed of as radioactive waste. In 1994, Chem-Nuclear began designing a pilot program, RECYGENTM, which targeted the centralized recycling of these radioactive ion exchange resins for reuse at the nuclear utilities from which they were generated. The technology for regenerating organic ion exchange resins is widely used in traditional water treatment but the use of this process presents difficulties when dealing with radioactive materials. The RECYGENTM process was developed with these potential problems in mind. In 1995, the first centralized pilot system for regenerating radioactive ion exchange resins was built and operated.

This paper will detail the operational aspects of RECYGENTM to reduce utility radwaste volumes. An evaluation of the concept, design, and operational aspects of regenerating resin for return to the utility will be discussed. The difficulties of the process will be analyzed such as mixed waste issues, waste by-products, and material handling. Performance data will be presented on the conditions of ion exchange resins received both chemical and physical, and their potential for regeneration, reuse and life expectancy. The utilities interface with the system and the limitations for resin receipt will also be discussed.

The Chem-Nuclear proprietary RECYGENTM process can provide utilities with a alternate method of handling spent radioactive resins. This system provides the utility significant advantages of radwaste volume reduction, cost saving for disposal, cost savings for new resin purchase, and an environmentally beneficial way of handling these spent resins.

INTRODUCTION

A new innovative process to treat radioactively contaminated ion exchange resins has been developed which adds a new aspect to an already existing technology. This process represents a hybrid of recycling and regeneration of radioactively contaminated resin used for water purification at Nuclear Utilities. These resin are processed off-site and returned for reuse at the utility. With ever-increasing disposal prices and uncertainties surrounding disposal site access, utilities continue to seeks ways to reduce the volumes of solid radioactive wastes generated. Organic ion exchange resins are used in a variety of water purification applications throughout nuclear plant systems. Traditionally, these resins which have contacted radioactive water have been used once and sent for disposal. The new process called RECYGENTM was developed to regenerate radioactive ion exchange resins for reuse in nuclear plant applications.Regenerating ion exchange resins has been a common practice for years in non-radioactive applications, but operational costs and waste by-product handling have prevented broad application of such technology to the nuclear industry. Using nuclear industry experience and knowledge in radioactive waste processing coupled with expertise from the commercial water treatment industry, the RECYGEN process was designed and constructed at Chem-Nuclear's consolidation facility in Barnwell, SC.

Using a process of regenerating radioactive contaminated resins for reuse, the utility can save on disposal costs of the resin, purchase costs of new resin, and can reduce solid radwaste volumes.

BACKGROUND

In developing a process to regenerated radioactivity contaminated resin, various aspects of the process and their potential problems had to be studied. The first step was to identify whether radwaste resins could be regenerated given the chemical nature of many radwaste systems which contain high suspended solids, high dissolved solids, detergents, and oils and greases. The regeneration of such resins was not a common practice. To test this potential laboratory bench top regeneration was performed. The results showed a definite ability for radwaste resins to be regenerated.

With this verified, a detailed study needed to be conducted to determine amounts and types of regenerate chemicals needed, the equipment required, and the amounts of waste generated. Most of this data was readily available from conventional water treatment sources. Detailed information was gathered on the types and weight amounts of regenerate chemicals required. Based on this information sodium hydroxide was chosen to regenerate strong base anion resins due to its availability and ease of handling. Hydrochloric acid was chosen to regenerate strong acid resin due to its availability and the high solubility of most chloride salts. The regeneration equipment evaluated was very simple requiring separation/regeneration vessels, a source of chemicals, and a source of demineralized water. In order to enhance the operability efficiency, it was decided to decouple the clean and separation portion of system from the regeneration portion of the system. This would allow the simultaneous operation of clean and separating and regeneration of resins. The study revealed the largest obstacle of regenerating ion exchange resins in a radioactive waste application as being the generation of large volumes of liquid wastes with high dissolved solid content. To address this problem, the study evaluated methods of volume reduction for the waste water problem.

Conventional regeneration systems generate between 50 and 100 gallons of waste water for every cubic foot of resin regenerated. This range is far from acceptable in a radwaste application. A system had to be designed which would reduce this range by at least half and the developed Recygen system would generate between 25 and 40 gallons of waste/cubic foot of resin regenerated. Several technologies were evaluated, including reverse osmosis, thermal concentration, and diffusion dialysis, to reduce the volumes of liquid needed for the process. The answer appeared to be a combination of recycling and thermal concentration.

Based on the study results and the technology evaluation, a radioactive regeneration facility was designed and constructed. The system process was composed of 6 major parts: 1) cleaning, 2) separation, 3) regeneration, 4) rinsing, 5) storage/packaging and 6) neutralization/thermal concentration. Each batch of resin undergoes processing through each phase as illustrated in Fig. 1.

Fig. 1

1. Resin received from the customer is sluiced from the receipt container to the cleaning vessel. During the sluice, a sample of the resin is taken for analysis of physical and chemical characteristics. A reverse flow rinse is introduced into the vessel expanding the resin and rinsing particulate from the resin. The rinse flow is returned through a filter

and back to the rinse water source where it is recycled back thus conserving water generation.
2. The mixed bed resin is then separated. The separation process is a combination of physical separation and chemically enhanced separation. This process produces almost complete separation with little or no mixed interface between the anion and cation resins.
3. The separated resin is then sluiced to the regeneration vessels where the resin is dewatered and rinsed. The resin is then filled with regenerate and undergoes several regeneration steps. The regeneration steps are integrated such that the regeneration chemicals can be utilized on multiple regenerations. This saves on chemical usage and reduces waste generation.
4. Once the resins have been regenerated they are again drained and rinsed. The rinsing at this stage is extensive and the resultant effluent from the resin must meet the set criteria. The first portion of the rinse water is discarded. The vast majority of the rinse is recycled back to the rinse water source. At the source, the rinse water is cleaned and returned back for rinsing. Recycling rinse water eliminates a significant volume of what otherwise would be waste.
5. After rinsing the resin is sluiced to a storage container where the resin is analyzed for physical and chemical characteristics. When the regenerated resin quality is verified, the resin is sluiced into packaged for return and reuse.
6. The final step in the process is the neutralization of regenerate chemical solutions. This neutralization is accomplished by controlled mixing of the hydrochloric acid and sodium hydroxide solutions. Once these solutions have been neutralized, they are pumped to the Thermex thermal concentrator where the liquid is reduced to a salt cake.

PROCESSING

To initiate the system, verify assumptions, and verify system procedures, clean non-radioactive resin processing was begun in August, 1995. After working out the procedural issues, several technical questions had to be addressed through the clean processing. The potential for mixed waste generation using acid and caustic, the regeneration potential, and waste generation volumes had to be solved. The mixed waste potential was easily solved as part of the process where the regenerate acid and base are combined and neutralized. The first process batch verified that the calculated regeneration chemical dosages would achieve the anticipated regeneration efficiency solving the second issue. The primary problem with initial assumptions was identified after the first non-radioactive regeneration batch. The production of waste water was higher than had been anticipated. Initially, all generated rinse water was to be recycled for reuse. It was found that higher chemical concentrations in portions of the waste made it impossible to recover all the waste waters. The minimization of these wastes became the focus of the clean testing.

A detailed chemical characterization was performed on rinse water batches as clean resin was processed. In the process, after resin is regenerated the resin is rinsed to a conductivity specification prior to return for reuse. The rinse water removes residual regenerate chemical to clean the resin. The intent of the rinse characterization was to identify at what point the rinse water could be recovered for reuse. Figure 2 and Fig. 3 reveals the chemical concentrations as the rinse procedure is conducted.

Fig. 2

As the characterization shows, the regenerate chemical concentrations in the rinse drop dramatically during the first part of the rinse. After the first portion of rinsing, the chemical concentrations level off to a reasonably low level. It was concluded that all rinse water, after the first portion, could be recovered for reuse. This conclusion would reduce the rinse water waste generation by 80%. With the rinse water waste volumes under control, the go ahead was given to proceed with radioactive resin processing.

Fig. 3

Low activity resins were acquired to provide an accurate radiation worker dose assessment. A contract was entered with a PWR station who would provide low activity resins for regeneration. These resins would be limited to <50 mrem/hr on contact. The resin provided was mixed bed, composed of 2 parts macroreticular strong acid cation and 1 part gel strong base anion. The goal in processing these resins would be to regenerate back to as close as a new resin specification as possible. The following in Table I are parameters similar to those used in a new resin specification.

Table I

The regenerating of resin to a new resin specification is impractical. As resin is used, physical and chemical degradation occurs. Physical stresses on the resin during use also causes cracking of some resin beads. The trimethyl functional group on the anion resin may slowly decompose leaving weak base sights or no exchange site thus reducing capacity. The polymer chains making up the resins undergo oxidation over time which can also reduce capacity.

For these reasons, used resin must be evaluated to determine the maximum practical extent to which resin may be regenerated with respect to new resin. A representative sample of the resin received is laboratory tested prior to processing through the Recygen system. These tests evaluate the physical condition of the resin and the potential to which the resin can be regenerated. Table II illustrates the analytical results for the initial condition of the low activity resin received.

Table II

The "As Received" resin results confirm the degree of degradation and/or irreversible fouling which has occurred to the resin. The cation resin analysis revealed little change over the new condition of the resin. The anion resin analysis, however, indicated a significant drop in capacity potential. The loss was 10-20% of new anion resin capacity. This could affect the number of regenerations which could be performed if this trend continued. This parameter will be monitored as this resin is received back for a second regeneration.

After analysis, the resin was cleaned, separated, and regenerated per the developed procedures. The regenerate chemical amounts used were in accordance with published literature which would achieve the highest practical regenerated resin capacities. The results of the initial processing is recorded in Table III.

Table III

RESULTS ANALYSIS

The results from the radioactive resin regenerations were very positive. The regenerated resin capacities reached 90% of potential and greater which was the target of the system. The amount of regenerate chemical to achieve these results were very close to the anticipated values. In an effort to investigate the amount of chemical needed to achieve higher

capacity regeneration, a laboratory regeneration was conducted. The capacity increase was plotted against the amount of regenerate chemical used. The results showed that 25% more regenerate chemical was need to achieve a 2% increase to 97% of the potential capacity. This would also require the elimination of recycling the regenerate chemical which would add dramatically to the waste volumes generated. Other alternatives such as varied flow rates and regeneration recycling did prove to increase the capacities without increasing regenerated chemical quantities.The capacities achieved in the process will be more than adequate for reuse in PWR radwaste treatment systems for which the Recygen system was designed. There is some question as to whether the regenerated resin could be placed back into a pure water application such as for secondary system use. The question can only be answered by an in plant test which has not yet been conducted.

The waste produced in these initial runs was slightly higher than anticipated. Approximately 40% more waste generated was contributed by the regeneration of a batch of resin than was anticipated. As processing continues the liquid waste generation will be reduced to the original assumptions. The liquid waste from the process is to be taken to a thermal concentrator where a volume reduction of 7 to 12 will be achieved. The thermal concentration of the waste has only been conducted on a single batch of waste where a volume reduction of 11 was achieved. As regenerating radioactively contaminated resins continues, the regenerated product can only get better. Familiarization with the process and small modifications to the process will provide increases in efficiency and reductions in wastes generated.

CONCLUSIONS

The goal of the CNSI RECYGEN process is to produce quality regenerated resins for reuse at the nuclear facilities. Initial regenerations of radioactively contaminated resins have proven the technology can achieve such quality of resins. These resin will have application in PWR and BWR radwaste waste water treatment systems and possibly in pure water systems. The use of the regeneration system can save the generator of these resins: replacement costs, and disposal costs while minimizing radwaste volumes. The CNSI RECYGEN system is an environmentally sensitive technology which will save the utility money.

11-5

RADWASTE VOLUME MINIMIZATION - DEVELOPMENT AND IMPLEMENTATION OF A PLAN FOR SUCCESS AT TVA NUCLEAR PLANTS

Lenon J. Riales
Tennessee Valley Authority

Mark S.Lewis
Chem-Nuclear Systems, Inc.

ABSTRACT

In the early 1980s, Tennessee Valley Authority's Browns Ferry and Sequoyah Nuclear Plants were among the highest low-level radwaste producing plants in the United States. Because of volume restrictions at the Barnwell disposal site, most of TVA's low-level radwaste was transported over 3,200 kilometers (2,000 miles) to the disposal facility at Richland, Washington. In order to reduce the transportation and economic impacts resulting from this large radwaste volume, TVA developed

a plan to minimize the generation of low-level radwaste and reduce the amount sent to disposal facilities. This plan involved benchmarking a number of "good" performers with a team of corporate and site radwaste professionals, determining which methods would work at TVA, and implementing the best volume minimization practices. Implementation involved up-front costs for new products and services and culture changes by the nuclear sites involved in the changes. Results sometimes took years to realize. Almost six years after initiating the plan, the results are staggering. Processing and disposal costs are down dramatically. Performance at TVA plants is now in the first quartile of radwaste generation for their reactor types.

Tennessee Valley Authority has three nuclear plants located in Tennessee and Alabama. Browns Ferry Nuclear Plant is located near Athens, Alabama and has three 1,100-megawatt General Electric BWRs. Currently two of those units are in operation. Sequoyah Nuclear Plant is located near Chattanooga, Tennessee and has two 1100-megawatt Westinghouse ice-condenser PWRs. Both units are currently in operation. Watts Bar Nuclear Plant has one completed 1100-megawatt Westinghouse ice-condenser PWR with no current plans to finish the second unit. The completed unit has a full-power license and is expected to be producing power soon. TVA has another two-unit nuclear plant near Scottsboro, Alabama (Bellefonte) but does not plan to complete these units at this time.TVA shipped its first low-level radwaste in October 1973 from Browns Ferry to Chem-Nuclear at Barnwell, South Carolina. Radwaste burial prices were cheap (about $0.02 per cubic meter or $0.75 per cubic foot), and there was not enough volume to cause concern. As all three units at Browns Ferry were started up and operated, it became apparent that at least one of the units would always be in a refueling outage with the associated large volume of dry active waste (DAW) that is generated. Operation of the three units put a strain on the common radwaste system and on the operating and support personnel in charge of keeping the system operating and the waste shipments traveling between the plant and the Barnwell disposal facility. One challenge was to dispose of the massive amounts of ion-exchange resin produced by the condensate demineralizer system. This powdered resin was difficult to dewater to meet disposal facility requirements. The need to make three or more shipments per week to keep up with the volume resulted in inadequate dewatering of the resin and subsequent violations from NRC and the State of South Carolina.

In 1979, the State of South Carolina restricted the amount of radwaste that TVA and others could send to the Barnwell disposal site to one-half of the previous year's volume. TVA was in the process of starting up the Sequoyah Nuclear Plant with the associated radwaste volumes usually encountered during start-up. Initially, both TVA plants had to store radwaste onsite because the TVA Board of Directors would not allow the nuclear sites to use the Beatty, Nevada or Richland, Washington disposal sites. Without large-volume storage facilities at Browns Ferry, areas in the Turbine Building, the stack, and other outside areas were used for storage. After permission was received to ship radwaste to the Richland site, the storage backlog at the sites was eventually reduced. For some time, over 75 percent of TVA's low-level radwaste was transported over 3,200 kilometers (2,000 miles) to the US Ecology disposal facility at Richland, Washington. Even though TVA then had a place to bury all of the radwaste that was generated at the two sites, we realized that we were

generating much more than we should in comparison to other similar nuclear plants.

In the early to mid 1980s, Tennessee Valley Authority's Browns Ferry and Sequoyah Nuclear Plants were at the top of the list of the highest low-level radwaste producing plants in the United States. Browns Ferry disposed of more than 3,800 cubic meters (134,000 cubic feet) of radwaste in 1983 and 3,600 cubic meters (128,000 cubic feet) in 1984 (see Fig. 1). Both of these numbers were more than 50 percent higher than the INPO median for three BWR units in those years. Sequoyah had both units in operation by 1984 and disposed of more than 1,048 cubic meters (37,000 cubic feet) of radwaste (see Fig. 2). Here again, this was more than 50 percent higher than the median two-unit PWR plant. At that time, radwaste disposal costs were relatively inexpensive and not a major concern for TVA. More emphasis was placed on power generation. High radwaste generation was considered an unfortunate byproduct of electricity production. At this time, Browns Ferry was making five or more large-volume radwaste shipments per week to the disposal facilities.

Fig. 1

Fig. 2

In early 1985 TVA voluntarily shutdown all of its operating units, three at Browns Ferry and two at Sequoyah. This shutdown was unrelated to its radwaste generation problem, although the radwaste problem was a symptom of the bigger management problems faced by TVA in the operation and maintenance of the large nuclear system. Many of the next several years were spent working to resolve the overall problem, and the radwaste problem was not specifically addressed. As can be seen from Figs. 1 and 2, the radwaste volumes at both Browns Ferry and Sequoyah decreased drastically beginning in 1985 as a result of the unit shutdowns.

As part of the overall "get-well" plan for plant recovery following the voluntary shutdowns, TVA began to focus on individual operating and maintenance problems. We realized that in order to have a healthy nuclear program, we would need to get our radwaste generation under control. In 1988, the volumes at Browns Ferry were well under the industry median. This was because Browns Ferry had no units in operation. At Sequoyah, the annual radwaste volume was more than twice the volume of a median PWR plant. As can be seen from Fig. 2, the radwaste volume at Sequoyah remained at or over the PWR median even though no units were in operation. In order for TVA to start-up any of the units and keep them operating properly, something would have to be done to reduce radwaste generation and the associated cost.

From April 1980 until October 1987, Browns Ferry received 24 NRC and state violations for radwaste packaging and shipment problems. Sequoyah received 6 NRC and state violations in radwaste during this same time period. Many of these violations were repeats of previous violations with root causes ranging from personnel errors to inadequate equipment to procedure problems. Several of these violations were as a result of inadequate dewatering of powdered condensate demineralizer ion-exchange resin. Many of these problems could be traced to the plants trying to make too many radwaste shipments too quickly because of the large volume generated. Between 1985 and 1988, a liquid radwaste and resin management plan was put into place in conjunction with Chem-Nuclear Systems to help resolve these problems.

In order to get a handle on run-away radwaste volumes and costs, TVA developed a plan to minimize the generation of low-level radwaste and to

reduce the amount sent to disposal facilities. The first step was to assemble a team of TVA radwaste professionals from the three nuclear sites and the corporate office in Chattanooga. This team would first determine the problems at each of the TVA nuclear plants. Then they would determine "good performers" in the nuclear industry. These plants would be benchmarked to determine if any radwaste minimization activities could also work at TVA facilities. The workable ideas would be tried to determine feasibility. A final report would be written to document the findings of the team and the potential benefit to TVA. It was realized at the start that the fix to TVA's radwaste problems would be costly and take many years. Many of the radwaste minimization problems were ingrained in the system to the point that only a culture change could correct them.

INPO and EPRI were contacted to determine which nuclear plants were considered good performers for benchmarking purposes. EPRI recommended Brunswick Nuclear Station as having a program which had made significant strides in turning around a program which "made electricity as a sideline to creating radwaste". INPO provided a list of BWRs and PWRs which had low radwaste volumes for the year 1988 or with a low three-year average from 1986 to 1988. From that list, Grand Gulf was selected for a benchmarking visit. Riverbend was also selected because of their use of oil decontamination methods. These three sites were visited in early 1990.

In addition to the benchmarking visits, Corporate Radwaste contacted five PWRs and seven BWRs from the INPO "good guy" list by telephone to determine their methods of minimization and volume reduction, staffing levels, methods of processing oily waste, and experience with vendors that contract for radwaste processing services. Based on the onsite visits, telephone calls, and a review of TVA training, site procedures for waste handling, and other plants' experience with offsite vendor processing, the TVA team put together a Volume Minimization and Reduction Plan (VMRP) for the nuclear plant sites in mid 1990. This plan centered around the reduction of DAW waste, since earlier contracts with Chem-Nuclear had started the process of reducing resin volumes through liquid and resin radwaste processing. The following actions were immediately implemented from the Plan:

1. A contract for the burning of contaminated oil was set up with Scientific Ecology Group (SEG).
2. Signs were placed at the entrance to regulated areas regarding the disposal of clean packing materials and other extraneous materials prior to entering the area. Disposal receptacles were placed near the signs.
3. The sites published awareness bulletins concerning the use of incinerable materials and the potential effect of offsite incineration on disposal costs and volumes.
4. Corporate Radwaste obtained a multisite contract for supercompaction which was awarded to SEG. This contract replaced a similar contract with Quadrex. A new multisite contract for DAW incineration was also awarded to SEG.
5. The sites began procurement of incinerable materials and reusable supplies (non-PVC) and would continue replacing non-incinerable and disposable stock items with these items.
6. The sites began more decontamination of floor and wall areas instead of exclusively utilizing disposable plastic coverings. When floor and wall coverings were used, certified incinerable plastic would be used.

7. The amount of contaminated area in the sites was greatly reduced. This, in turn, resulted in less radwaste since work in clean areas did not produce as much contaminated waste.
8. Use of the site hot tool room increased. This resulted in fewer tools to decontaminate and fewer tools and other equipment shipped as radwaste.

In addition, the following recommendations were made in the Plan:

1. The Technical Training staff should modify Level II GET training lesson plans to incorporate identified improvements to the radwaste minimization portion of the course.
2. All initial and retraining GET courses should adopt the REDUCES concept for teaching radwaste minimization at the sites.
3. All upper-tier site minimization procedures should be updated to include the findings of the TVA team.
4. Site management should incorporate radwaste goals into each section manager's goals program for sections that generate radwaste.
5. Site management should appoint a radwaste minimization liaison to aid in the preplanning of major tasks that generate radwaste and routinely monitor work practices for impact to radwaste volumes and cost.
6. Site management should implement methods of penalizing willful violations of minimization practices.
7. The nuclear sites should implement a liquid segregation program which would provide a mechanism for the sampling and proper disposition of oil and other liquids.
8. The sites should continue to provide visual aids for employee education depicting the volume of radwaste shipped, processing and disposal cost, and violations incurred.
9. Sections which generate radwaste at each site should be charged for disposal of their waste directly rather than having the site radwaste organization budget for the entire site. This would put the emphasis for volume minimization directly on the generators of the radwaste.
10. Front-end source term minimization and reduction techniques (such as stellite control, chemical decontamination, constant elevated pH, and improved filtration) should be evaluated by each site and implemented as needed.
11. Work on contaminated equipment at the sites should utilize containments instead of setting up contamination zones.
12. Technological enhancements for equipment or methodologies should continue to be explored by the nuclear sites and corporate staff.
13. The sites should continue with the successful reduction of resin volumes through liquid and resin processing conducted by Chem-Nuclear Systems.

Many of the easy recommendations were implemented quickly and began to show positive results. However, the TVA team quickly realized that TVA plants were in a "Catch-22" situation. The largest problem was the high volume of dry active waste. Until TVA could come to grips with the onsite minimization problem, the obvious answer was either offsite incineration, offsite supercompaction, or a combination of the two. But much of this waste contained PVC (plastic sheeting, bags, and other disposable items) which could not be sent to the incinerator because of resultant hydrochloric acid production in the incinerator's scrubber system. The use of offsite incineration depended upon removing all sources of PVC from the plants and substituting equivalent non-PVC products. This substitution took years to accomplish since many of the warehouses were full of PVC items and workers were use to using the old PVC items. In

some cases, non-PVC substitutes were not available for purchase or were not as reliable as the well-known PVC products. The use of offsite incineration at SEG was delayed for years until certified incinerable items were in complete use at the two sites.

In 1990, the Senior Vice President of Nuclear Power set a Level 1 goal requiring TVA nuclear plants to be at or below the INPO average for radwaste volume. TVA was to maintain this goal every year regardless of plant evolutions. Increased emphasis from site management to reduce radwaste-related costs was a large factor in changing the culture and gaining support from site workers. Other factors included:

1. The use of bulk material permits before large quantities of plastic, wood, or other bulk materials would be allowed into the regulated area.
2. The introduction of reusable or recyclable materials for previously disposed items.
3. Use of onsite and offsite decontamination of tools and equipment . Much of this material was disposed of as contaminated in the past.
4. Improvement in worker education and awareness of radwaste costs and volume impacts.

Onsite segregation of contaminated from noncontaminated waste was tried for some time at Browns Ferry. Plant laborers and RADCON technicians were used to sort through yellow bag trash to determine which items were contaminated. Noncontaminated items were disposed of with the green bag trash. Much of the pay-back from this practice came from the location and reuse of tools and equipment found in the radwaste. This practice was discontinued at Browns Ferry because it was labor intensive and costly.

One of the biggest impacts on DAW generation was the reduction in the amount of contaminated area in the plant. At Browns Ferry, the percentage of contaminated area in the plant decreased from a high of 14.7 percent in 1989 to the present value of 0.75 percent. At Sequoyah, contaminated area has been reduced from a high of 13.7 percent in 1990 to the present value under 3 percent (at the end of the unit 1 refueling outage). This means that more of the plant can be accessed and worked performed in street clothes without the volume impacts associated with contaminated zones. It also means that equipment leaks that cause many of the zones have been reduced as well as the associated introduction of contaminated water that must be processed by plant and vendor systems. Reduction of contaminated plant areas is one of the first steps to getting control of the radwaste problem at a plant.

Although the use of offsite compaction and incineration systems is very important, the real indicator of improvement is a reduction in the amount of radwaste generated. At Browns Ferry. total DAW generation has reduced from 2,400 cubic meters (85,000 cubic feet) per year in 1993 to less than 1,700 cubic meters (60,000 cubic feet) at the present time. At Sequoyah, the amount of DAW generated has decreased from 2,800 cubic meters (100,000 cubic feet) per year in 1991 to 566 cubic meters (20,000 cubic feet) at the present time. During this time, unit refueling outages at these sites have produced less DAW than the previous outages. This indicates that we are getting better at doing the same work while making less waste each time.

Dealing with the ion-exchange resin generation problem at the plants was somewhat easier than the DAW problem. At Sequoyah, annual resin generation volume has now dropped from a high of 227 cubic meters (8,000 cubic feet) in 1985 to the present value of less than 28 cubic meters (1,000 cubic feet). This decrease can be attributed to better plant

chemistry, the efforts of an excellent site radwaste staff, and a dedicated vendor crew utilizing Chem-Nuclear's ALPS water processing unit. Payment for water processing at the site is based on the number of gallons of water processed rather than the number of hours worked or the volume of resin generated. This provides an incentive for Chem-Nuclear to optimize the throughput of the resin to produce the quality of water required by TVA. It has worked to the advantage of both Chem-Nuclear and TVA to minimize the resin volume.

At Browns Ferry, the amount of ion-exchange resin generated is below the best quartile value for a two-unit BWR. Most of this success is due to changes in the condensate demineralizer precoat system and new technology in the use of filtration at the plant. Credit also goes to the use of the Chem-Nuclear RDS-1000 resin drying system run by a Chem-Nuclear operator at the site. This system is responsible for reducing the amount of resin volume sent for disposal through its drying system and for eliminating the potential for excess water in Browns Ferry's resin shipments to Barnwell. Browns Ferry received three violations and fines for having excess water in its dewatered resin from 1980 to 1987. There have been no violations since use of the RDS-1000 began in 1988.

In July 1993, TVA and Chem-Nuclear Systems entered into a long-term Radwaste Services Partnership to provide a full scope of radwaste services and equipment to TVA nuclear plants and other facilities. The goals of this partnership were to keep radwaste volumes and costs as low as possible while providing quality processing and disposal services to TVA plants. In the first 2 years of the Partnership, millions of dollars of processing and packaging savings have been realized by TVA. As a result, Chem-Nuclear recently received the 1995 TVA Suppliers Excellence Performance Award for their innovations and cost reduction achievements as a supplier and Partner to TVA.

Almost six years after initiating the Volume Minimization and Reduction Plan, the results are staggering. After receiving 30 NRC and state violations from 1980 to 1987, neither Browns Ferry or Sequoyah has received a radwaste violation since October 1987. Corporate and site radwaste goals are now used to determine employee and management incentive bonuses. Processing and disposal costs are down dramatically. TVA plants are now in the first quartile of radwaste generation for their reactor types. Sequoyah has been at or within the best quartile since 1992. This turnaround in the radwaste management problems at TVA nuclear plants required much work by the site and corporate staffs and a commitment at all levels to make it succeed. However, the results have been worth the hard work, and the program is healthier than it has been in years.

RETRIEVAL, PROCESSING AND PACKAGING OF RADIOACTIVE WASTES

Roger E. Streatfield
Magnox Electric
Technology and Central Engineering Division
Radiological and Environmental Technology Branch

Berkeley, Gloucestershire, United Kingdom

ABSTRACT

Within the UK Electricity Supply Industry in England and Wales there are six operating Magnox and five Advanced Gas Cooled Reactor (AGR) stations,

a PWR at Sizewell B and two Magnox stations undergoing decommissioning. The Sizewell B PWR has recently started commercial operation, and is equipped with a plant for the routine encapsulation of Intermediate Level Wastes (ILW). An extensive program of research and development has been carried out over a number of years, augmented by on-going sampling and analysis, in order to formulate a cement based encapsulating medium for all wastes.

Over the 30 year period of Magnox reactor operation a number waste materials have been produced, and those classified as ILW are retained in storage facilities at the stations. Some of the materials are no longer commercially available, and a suitable simulant must be identified before any formulation development work can be carried out. In addition, the design of the early Magnox reactors did not permit a high degree of waste segregation, and consequently some waste storage facilities contain a number of different materials which could have undergone physical/chemical change. The situation at the AGR stations is characterized by lower waste arisings and improved segregation. In addition, most of the materials which make-up the waste are still commercially available which simplifies the selection of a simulant for development work.

Successful formulation is measured against a number of criteria, all directed at producing a satisfactory wasteform which will have acceptable physical and chemical properties in the post-closure repository environment. Properties measured include dimensional stability, weight change, tensile strength, elastic modulus, pore water chemistry, the effect of radiation, exposure to water and freeze/thaw conditions. This is complimented by an extensive program over a number of years to monitor the potential for corrosion of the waste container. It is also essential to take account at the formulation stage of aspects such as heat evolution, rheology of the cement mix, retrieval of the waste and application to an encapsulation plant.

Materials which would be expected to have an affinity with a cement based medium have in general represented no particular problem with high waste loadings readily achieved. Other materials, such as phenol formaldehyde based resins, have shown a propensity for expansive phase formation under irradiation resulting in physical failure of the wasteform. Some ion exchange resin wastes, in a formulation with a high sodium hydroxide content to offset the inhibition to setting caused by the presence of boron, exhibited failure under water immersion. A number of wasteforms have appeared to fail under radiation exposure, although modelling suggests that the mechanism is a combination of radiolytic gas generation and the limiting diffusion rate through the cement matrix. These issues have now been resolved and the emphasis has moved to the development of a methodology for the encapsulation of the retrieved wastes, which in a number of cases will consist of an homogenized mixture of materials. There is a significant generic element to the methodology database, particularly where the technology has been underwritten by more fundamental studies on the underlying physics and chemistry. Experience has been obtained with techniques to improve the strength of the wasteform, and the potential effect on the wasteform of a variety of low concentration materials such as oils, de-greasing agents and detergents, decontaminants and superplasticisers. This body of information, which includes some novel formulations, therefore represents a valuable contribution to the requirements of utilities with all types of waste.

The overall conclusion is that sufficient experience has now been accumulated to enable real retrieved wastes to be encapsulated in a cement based media which is highly compatible with the required repository environment. This can usually be achieved at a high, and therefore economic, waste loading. The formulations have also shown themselves amenable to modification in order to accommodate a particular feature of a waste or property required of the wasteform.

BACKGROUND

In the privatization of the UK Electricity Supply Industry in 1990 the nuclear component in England and Wales was retained in the public sector under the name Nuclear Electric plc (NE). NE assumed responsibility for the operation of the Magnox stations (two of which are now undergoing decommissioning), five Advanced Gas Cooled Reactor (AGR) stations and completion of the Sizewell B PWR. Since 1990 NE has continued to develop a comprehensive strategy for the management of radioactive waste arisings from the operation and decommissioning of nuclear power stations (1). The nuclear component of the UK Electricity Supply Industry is now being further privatized, with the Magnox reactors remaining in the public sector.

This paper is a logical follow up to the paper given to the WM'95 Conference (2), in which a broad overview was given covering waste types, work on encapsulation techniques, the intentions with respect to encapsulation plant and some of the novel technologies which were being developed. The intention here is to update the position for Magnox, AGR and PWR intermediate level wastes (ILW)a, and focus on some of the more intractable areas where satisfactory encapsulation formulations have now been developed. It should be noted that low level waste (LLW) is routinely disposed of to a shallow land burial site in the UK operated by British Nuclear Fuels plc.

ENCAPSULATION OF SOLID ILW IN CEMENT FORMULATIONS

At present operational radioactive ILW arisings at power stations are held in special accumulation facilities pending eventual retrieval and disposal. It is both national and company policy that disposal will be by deep land burial in the proposed NIREX Deep Waste Repository (DWR). To ensure the safe handling and transport of the wastes between retrieval and emplacement in the repository, it is intended that they will be encapsulated in a suitable matrix contained within a NIREX approved container. The encapsulation matrix will be cement based, as this material has a number of advantages, although the option to use an organic polymer is still retained and may be used as a one-off to encapsulate some ion exchange resins at Trawsfynydd power station which is undergoing decommissioning. Although cement is a cheap, well tried and tested material such that its handling and general mechanical and chemical properties are well known with a wealth of practical experience on which to draw, there are other factors which need to be borne in mind concerning how cement based formulations are predicted to behave within the repository.

In developing this cement based approach to the encapsulation of ILW the following issues have been continuously reviewed, as it is important to the long term integrity of the product that the optimum cement formulation is chosen for each waste, whether a single material or a mixture.

- availability of novel cement based formulations to offset a particular problem.

modification of the cement set process and the wasteform properties by waste/cement interactions.

achievement of a particular cemented wasteform characteristic with chemicals and other additives.

formulation development compatible with a full scale operational and active encapsulation plant.

Nuclear Electric's Intermediate Level Wastes

The ILW which NE will have to encapsulate can be summarized as follows, noting that there are also minor amounts of a number of other materials present.

Magnox Stations:

Magnox fuel element debris

Magnox sludges

Active Effluent Treatment Plant (AETP) sludges

Oily wastes (especially oily sludges)

Inorganic ion exchange materials

Organic ion exchange resins (2 main types)

AGR Stations

Borated ion exchange resins

Active Effluent Treatment Plant (AETP) sludges

Filter pre-coat materials

PWR Stations:

Boric acid concentrates

Borated organic ion exchange resins (similar to those at AGR stations)

Filter elements

The amounts of ILW currently held at NE's stations are comparatively modest and are typically a few tens of m3 for any individual waste (except at Trawsfynydd where the holdings of spent ion exchange resin are a few hundreds of m3) (3).

REQUIREMENTS OF THE CEMENTATION PROCESS

Retrieval

It is assumed that all ion exchange resin and sludge type wastes held in storage will be retrieved by homogenizing the contents of a tank and hydraulically transporting the mixture to a secondary vessel or the encapsulation plant. This is particularly the case with the accumulation facilities on the earlier Magnox stations which may contain a number of waste types. In such instances the cement formulation must be able to encapsulate the mixture of wastes and, allowing for the possibility that the wastes may not be homogeneously mixed when retrieved, the formulation should ideally be able to accept the extreme of 100% of any one component. This is potentially quite a severe constraint, but as yet has not proved insurmountable, and in most cases represents a very unlikely situation. There is the additional point concerning the water content of the retrieved waste and whether de-watering is required before encapsulation.

Mixing

In the application of a cement encapsulation process, where waste and other ingredients such as Ordinary Portland Cement (OPC) and Blast Furnace Slag (BFS) are dispensed into the container and mechanically mixed with water to form an homogeneous mixture, heat is evolved which will assist the hydration process and the mixture will become more viscous over time until the initial set occurs. It is usual to measure the torque required by the motor turning the mixing paddle, and for two

speeds to be used for the mixing process, a lower speed while the ingredients are being dispensed into the container to minimize splashing, and a faster speed to ensure homogeneity. The composition of the mixture, and the rate at which initial set occurs must therefore be such that an homogeneous mixture is formed before the viscosity starts to increase significantly. This represents another area of potential constraint on the cement formulation.

Heat Evolution

In the encapsulation of radioactive waste in cement based formulations, some account must be taken of the heat evolved. In terms of the specific heat of hydration the reaction of the aluminate phase is most exothermic, followed by alite, the ferrite phase and belite. The bulk of the heat, however, arises from the alite C3S component, because it is the major constituent. One simple way of reducing the heat generated is to dilute the C3S component with other cementitious materials which contain small percentages of C3S. Two such materials are pulverized fuel ash (PFA) and BFS and both have found use in formulations for NE's wastes. The temperatures developed in some typical laboratory experiments for various ratios of OPC to BFS are shown in Fig. 1. It is worth noting how the heat is released earlier in the OPC-rich mixes than in the BFS-rich ones, due to acceleration of the rate of the hydration reaction by heat. For practical purposes it is found necessary to have a least 7:3 BFS/OPC and in general 9:1 BFS/OPC is specified for use with NE's wet slurry wastes. One consequence of the use of high slag or BFS cements is that the range of available water/cement ratios is rather less than would be the case with pure OPC. This is illustrated in Fig. 2 where the range of acceptability in terms of the ability to mix and the presence of bleed water or failure to set narrows increasingly as the %BFS increases. This also restricts the range of the water/cement ratio.

Fig. 1

Fig. 2

NE's mobile encapsulation plant will utilize containers ("liners") with a capacity of 2.6 m3. Such a large volume of cement can lead to problems with excessive heat generation as noted above and to ensure that this does not happen the cement formulation must be selected carefully.

Application to an Encapsulation Plant

A cement formulation suitable for a particular waste will have been developed on a small scale initially and then taken to the 10-20 litre scale for the product evaluation work and the production of specimens for testing. If a particular problem concerning handling or mixing is envisaged some testing may be carried out at full scale.

Eventually the cement formulation, in terms of weight of cement and BFS and volumes of waste slurry, mix water and other ingredients, will be programmed into the control system of an encapsulation plant for automatic dispensing during a production run on active waste. Is essential to know the expected level of plant error bands, the repeatability of the system in terms of valve opening times and pump delivery quantities per stroke or revolution. Also the volumes of all vessels used to store or dispense materials, the volume of any spaces where "hold-up" can occur and the implications of all flushing operations. In this way the parameters of the plant can be taken into account and the formulation adjusted if necessary to ensure that the containers do not over or under fill and that the wasteform is satisfactory when set. This is another area of potential constraint on

the cement formulation, as it must be flexible enough to accommodate such modifications.

The plant throughput must also be such that containers are not moved until after the initial set has occurred, in order to avoid the possibility of the formation of cracks or fissures. Although the wasteform is not fully hydrated by this time it is sufficiently free of liquid water that the crack or fissure will not self-heal, and the wasteform is therefore cracked and in a failed condition from the start.

Due to the quantities of waste involved it is not considered cost effective to construct and retro-fit a waste encapsulation plant at each existing station and it is intended that a mobile encapsulation unit will be available. Sizewell B has a dedicated encapsulation plant and this is the intention with any future stations. In order to achieve the required throughput it is important that the cement hardens sufficiently quickly, as storage capacity for drums set aside to harden is limited and a maximum set time of 16-24 hours is envisaged. There is also a requirement that there be no standing or bleed water on the product after set has been achieved, and this places an upper limit on the acceptable water/cement ratio. The process will be in-drum mixing with a sacrificial paddle, and as the mixing torque requirement is a function of the viscosity of the mixture, it imposes an additional constraint which sets the lower limit to the water/cement ratio.

REQUIREMENTS OF THE CEMENT FORMULATION DEVELOPMENT

Cement Chemistry

The chemistry of cement both during set, curing and subsequent longer term hydration is complex but fairly well understood in terms of the main physical phases and the overall micro-structure. The important issue in the cementation of a variety of radioactive wastes is the potential for the formation of unstable cement monoliths. This can range from spalling, which may be at a tolerable level, to fracture and crumbling of the monolith which is not acceptable. This in turn can be due to physical/chemical mechanisms such as radiolytic gas generation or the formation of an expansive phase.

Sampling/Analysis and Simulants

There is some physical and chemical data available on most of the wastes, however this is not always comprehensive enough and there is an on-going program of sampling and analysis. The identity of the waste can often be obtained from station records, although one difficulty not apparent in the list of waste types given earlier is that several different materials may occur together in the same waste accumulation facility.

Development work is not usually carried out on active waste and it is necessary to identify a number of simulants. If the waste material is still available it would be used in the "as received" condition, unless there was specific knowledge of physical or chemical degradation in storage, in which case this would be simulated. An example is particle size reduction of a material during use. If the material is not available commercially, as with granular Lewatit DN ion exchange resin, then either remaining sources must be located or a simulant material identified. The simulant must be chosen carefully in order not have any significant deviations from the expected behavior of the actual waste during cement encapsulation and the product evaluation testing.

A category of waste for which simulation is the only way to proceed is sludge from the Active Effluent Treatment Plant (AETP). Based upon the origin of the AETP input flows, including filter backwash, dirty drains,

washrooms and laundry, up to twenty materials are required to simulate a sample of AETP sludge. One of these is oil which acts as a binder for the sludge.

Wasteform Properties

Adequate mechanical strength: great strength is not required but it must be adequate for handling and transport, which means that the container/wasteform must pass the appropriate drop tests.

Dimensional stability: some cements expand as they set, imposing stresses on the container which may effect its integrity. Excessive contraction is also undesirable as this potentially allows water access to the container which could lead to enhanced corrosion.

Monolithic block: the wasteform must set to give a monolithic block free of cracks or loose material.

Minimal inside-out corrosion of drum: whilst the cement remains in contact with the drum, corrosion is likely to be minimal (the cement maintains a high pH environment) unless excessive quantities of corrosive anions (such as chloride) are present in the waste. Outside-in corrosion is a function of the storage conditions and has no bearing on the wasteform properties.

Fire resistance: must be able to withstand a standard fire test.

Low leachability: if the wasteform comes into contact with water, for instance, in an accident whilst being transported to the repository, or ultimately, in the repository itself, radionuclides must have a low leach rate. This condition is usually easily achieved if the wasteform maintains its integrity (cracking/fissuring/crumbling etc. increases the surface area, and may release active particulate).

Minimal gas evolution: gas may be evolved either through radiolysis of the water in the cement or due to corrosion of metallic materials such as Magnox. Gas evolution under such circumstances at a realistic repository dose rate is unlikely to cause cracking of the cement (due to the build-up of gas pressure in the micropores of the cement). However, since one of gases evolved is hydrogen, this may represent a safety hazard in addition to leading to drum pressurization. Fortunately at the doses likely to be received from NE's wastes these problems are of little importance, and there is always the design option of a vented drum.

Resistance to radiation: the cemented wasteform will be exposed to a predicted dose rate of about 20 Gy h-1 in the repository from self-irradiation and irradiation from adjacent wastes. The whole life repository dose is estimated to be 9 MGy. In order to achieve the whole life dose, irradiation tests have to be accelerated and as will be explained this can lead to experimental problems.

SUPPORTING DEVELOPMENT AREAS

Long Term Monitoring of Cemented Wastes

A large number of samples are included in this long term monitoring program, and dimensional stability and other physical properties are updated annually for the following wasteforms:

Fine and coarse Magnox sludge
Bead Lewatit DN ion exchange resin
Ammoniated IR-120 ion exchange resin
Decalso Y
Granular carbon types 203C and 207C
Dicalite Speedplus
Cemented AW500 inorganic ion exchange material
Magnox splitters

Borated wastes such as ion exchange resins
PWR primary ion exchange resin
AGR silica gel resin
PWR wastes such as boric acid concentrate

Corrosion of Waste Containers

A number of 50 litre containers have been instrumented to monitor the in-drum environment in terms of the corrosion potential, oxidation potential, galvanic current, relative humidity, temperature and corrosion rate. The containers are stainless steel or carbon steel and are either vented or sealed. Each container is filled with a simulated waste in the appropriate cement formulation, followed by a capping grout and a lid. Following a period of monitoring the containers are sectioned, the instruments recovered and the internal surface of the container subjected to detailed examination. Table I lists the containers monitored to date. The sealed containers, with the exception of number 1 (boric acid evaporator concentrate simulant in a stainless steel container), are continuing to show anaerobic potentials. The move to aerobic potentials in the stainless steel container (number 1), is associated with micro-cracking of the wasteform allowing air penetration. The destructive examination of container number 4 (boric acid evaporator concentrate simulant in a vented carbon steel container) confirmed that conditions within the drum were reducing and not corrosive.

Indicated corrosion rates are between 0.02 and 10 mm year-1. Times to penetration assuming uniform corrosion from inside only are 280 years for the mild steel container and over 15,000 years for the stainless steel container. However localized corrosion will reduce this time considerably. Corrosion rate measurements will continue on the remaining six containers in order to underwrite the envisaged minimum lifetime of 50 years.

Table I

Magnox/graphite/alloy Combinations

This work was undertaken to identify any particular combinations of materials that could give rise to enhanced rates of corrosion when electrically/chemically coupled. The materials used to set-up galvanic couples with Magnox were graphite, cast iron, zirconium, 316 stainless steel and Nimonic springs as shown in Table II, all with appropriate degreasing and surface treatment. In addition two 50 litre stainless steel containers were instrumented to monitor the galvanic corrosion current between Magnox and graphite, corrosion and oxidation potential, relative humidity of the air in the container void, temperature within the wasteform and on the container surface, and the corrosion rate of a single Magnox electrode. In all cases the containers were filled with 3:1 BFS/OPC with a w/c ratio of 0.39.

Table II

It was concluded that galvanic coupling of Magnox to graphite is unlikely to result in significantly higher rates of hydrogen gas generation, the long term corrosion rate for Magnox/graphite couples is <0.01 m year-1 and that the oxidation potential of the wasteform indicated that conditions in the cement were oxidizing throughout the test duration. Physical examination showed that exposure of Magnox to a cement environment resulted in a protective surface film of Mg(OH)2 and the inside walls of the stainless steel container showed no signs of corrosion after greater than 6000 hours exposure to a 3:1 BFS/OPC (w/c =

0.39) grout. Over the test period of up to 250 days, mixed graphite and Magnox in a cemented matrix showed no propensity for enhanced corrosion.

Assessment of Superplasticisers

The literature suggests that the correct use of these materials will give increased fluidity without any adverse affects on the long term wasteform properties. Only sulphonated naphthalene formaldehyde (SNF) type superplasticisers are assessed as possessing negligible complexing ability and are therefore preferred as they would not enhance radionuclide mobility in the repository post-closure situation. Experiment has shown that it is essential to use these materials within the manufacturers recommended concentrations, otherwise poor process and product properties result. The conclusion of the tests was that the use of SNF type superplasticisers within prescribed limits, will not result in any deleterious long-term wasteform properties.

Assessment of Detergents, Decontaminants and Other Agents

Power stations use a number of materials for cleaning and decontamination processes, some of which will enter radioactive waste streams and could result in low concentrations in the retrieved waste for encapsulation. The objective of this and other studies is to prove that credible concentrations of such materials in typical waste streams will not adversely effect the encapsulation process or the long term stability of the wasteform.

A typical decontaminant liquor would contain sodium citrate, EDTA and active detergent in a sodium sulphate carrier. The detergent would typically consist of sodium alkyl aryl sulphonate, ethoxylate non-ionic alcohol, sulphate, chloride and other salts in a water based carrier. Nitric acid decontamination liquor neutralized with sodium hydroxide was also included, in addition to other decontamination solutions containing potassium permanganate, nitric, citric and oxalic acid. The composition of some AETP simulant sludges includes commercially available detergents and decontaminants. Some detergents are based upon mixtures of chemicals such as nonyl phenol ethoxylate, sodium salts of EDTA, sodium tripolyphosphate, sodium carboxy methyl cellulose and sodium sulphate, while others are alkaline and based upon biologically soft surface active agents and sequestering agents. Other commercially available materials consist of sodium metasilicate, sodium carbonate, trisodium phosphate, low foaming surfactants, anti-foaming agents and a sequestrant. Specific anti-foaming agents have been examined separately. The overall conclusion from this comprehensive body of information is that there will not be a problem with the encapsulation in cement of radioactive ILW containing such materials at anticipated concentrations. However, long term degradation of organic species may need further consideration. The high pH of the cement environment and the low concentration of these organic materials (and their degradation products) probably represents a satisfactory situation with respect to the repository post-closure safety case.

This work was directed at commercially available detergents/decontaminants which will be used at nuclear power stations normally in a form diluted with water to 10 vol% although more concentrated solutions may have particular applications. The conclusion from the small scale testing and product evaluation studies is that these materials can be encapsulated satisfactorily in a 9:1 BFS/OPC cement blend with up to 100 volume per cent of the water volume replaced by the detergent/decontaminant, and with no adverse effect on the waste product

properties up to 90 days. Properties of these cemented wasteforms will be monitored long term.

WASTE-CEMENT INTERACTIONS

Having reviewed briefly the major constraints on the encapsulation process and factors influencing the selection of cement formulations, there remains the subject of waste-cement interactions. Some wastes can be incorporated into cement at acceptable loadings without difficulty, but others require special pre-treatment or the addition of other chemicals to modify the chemistry during or after setting. This will be illustrated by reference to two specific waste streams, boric acid and Lewatit DN ion exchange resin. Boric acid concentrates will arise at the Sizewell B PWR, and an understanding of how boric acid interacts with cement is essential to the treatment of this waste and the successful incorporation of borated resins (which arise at both AGR and PWR stations) into cement. Lewatit DN is a phenol formaldehyde type ion exchange resin which has been used on Magnox stations, and which has proved difficult to successfully encapsulate in a cement based formulation due to its unique properties.

Encapsulation of Boric Acid and Borated Resins

The well known effect of boron (and other inorganic salts) in retarding the process of cement set is illustrated in Figs. 3 and 4, where quite modest amounts have a considerable effect on the time to set as measured by the exotherm and the cement strength as measured by the ultrasonic pulse velocity. A typical PWR boric acid concentrate will be 12% by weight (though concentrations up to 24% may be produced) and with such a concentration cement does not, for all practical purposes, set. The borated resins will be of the divinylbenzene (DVB) type and will arise at all power stations from pond water ion exchange plant, although the most active will be from the PWR CVCS system. The formulation must be able to encapsulate all extremes from 100% anionic to 100% cationic resin.

Fig. 3

Fig. 4

The mechanism of delayed setting is the formation of an amorphous calcium borate phase of composition CaO.B2O3.6H2O around the grains of cement, hindering normal access of the porewater. This effect may be overcome by preventing the formation of the solid calcium borate phase by either keeping the boron in the aqueous phase or removing the boron into a solid phase other than calcium borate.

Initial work was directed at keeping the boron in the aqueous phase, and study of the [Ca(BO2)2.2H2O-Ca(OH)2-H2O] system indicates that a high (OH)- concentration increases the solubility of Ca(BO2)2.2H2O. There is also an increased rate of hydration in the presence of NaOH as indicated by the evolved heat. Therefore the use of sodium hydroxide additive would keep the B(OH)-4 monoborate ion in solution and replace the calcium borate with calcium hydroxide through which the porewater could diffuse. For the PWR boric acid concentrate, experiments have shown that in 9:1 BFS/OPC mixtures the optimum NaOH:boric acid ratio is 2.5:1 to achieve set in 16 hours, and this simple approach works well in overcoming the retarding effects of boric acid. This type of wasteform was satisfactory in all respects except resistance to irradiation.

The problem with radiation testing is that in order to achieve the estimated whole life repository dose of 9 MGy it is necessary to use accelerated irradiation testing, and this means using a dose rate of 2,000 Gy h-1 or greater in order to complete a total dose of 9 MGy in a

suitable time period such as 3 or 6 months. Radiolytically generated gas in the pore structure of the set product was unable to escape at the required rate and caused pressurization of the internals leading to fracture. The gas generation rate is a function of the dose rate (about 2x104 Gy h-1) and this is much greater than the predicted dose rate in the repository (20 Gy h-1). Subsequent work established that by limiting the boric acid loading to 12 wt%, allowing the product to cure for over 100 days and reducing the dose rate for the accelerated irradiation tests, a satisfactory resistance to irradiation up to the whole life repository dose of 9 MGy was achieved. Therefore, the product obtained by incorporating 12% boric acid in 9:1 BFS/OPC is able to meet all targets.
With borated resins, the first formulations contained up to 21.5 wt% borated IRN 150L resin in a 9:1 BFS/OPC (w/c = 0.3) mixture with 47 wt% NaOH (approximately 13 Molar). The wasteform was acceptable in all respects except underwater stability, where degradation of the wasteform was caused by resin bead swelling due to the presence of large NaOH concentration gradients. Subsequent work demonstrated that with a reduced waste loading of 10 wt% in 9:1 BFS/OPC (w/c = 0.33), the NaOH concentration could be reduced to 5.5 wt% (approximately 2.1 Molar mix water) and the wasteform was stable to underwater immersion.
It was therefore necessary to develop an alternative system which could return to waste loadings greater than 10 wt% while still meeting all the requirements for the properties of the wasteform. Further development work identified the mix consisting of 20 wt% borated IRN-420 or IR-120(Na+) resin in 9:1 BFS/OPC with 6 wt% (of the cement powder) of high alumina cement (HAC) (w/c = 0.37 and 0.50) using 1.5 Molar NaOH mix water. The role of the HAC, as for the NaOH, is to prevent retardation of the OPC hydration by boron. The calcium aluminate phases from the HAC react with B(OH)4- to form a solid boron containing phase which does not hinder access of porewater to the cement particles.
However, this formulation showed unacceptably poor compressive strength development at 2 days for 25 wt% borated IRA-420 in a cement formulation of 9:1 BFS/OPC + 6 wt% high alumina cement (HAC) + 1.5 Molar NaOH mix water over the range of water/cement ratios. This would give problems in moving the cemented waste without causing fracture. Although beyond 2 days and up to 90 days strength development, dimensional stability and underwater stability were acceptable, this formulation was unacceptable. The maximum waste loading for 100% borated resin is therefore limited to 20 wt% until the level within the range 20 to 25 wt% is located in terms of the 2 day compressive strength. A 25 wt% resin loading is suitable for IR-120 (Na+), primary circuit resin and secondary circuit resins, in terms of mixing characteristics, set, 24 hour bleed, compressive strength, dimensional stability and underwater stability to 90 days.
Irradiation tests used 20 wt% IRA-420 or IR-120 (Na+) in a 9:1 BFS/OPC mix with 6 wt% HAC and 1.5 Molar NaOH mix water, and as with the boric acid concentrate wasteforms, samples split into several pieces after a dose rate of 10,000 Gy hr-1 to a total dose of 6 MGy. The mode of failure (several large pieces) was not the same as the observed failure mode for cemented Lewatit DN under irradiation (which was more of a disintegration into a coarse powder), and there was no evidence of the expansive phase formation for the borated resins, noting that the cationic resins contain a sulfonic acid group. It was therefore suspected that the wasteform failure mechanism was, as with the boric acid samples, the radiolytic generation of gas within the wasteform at a rate too great for normal

dissipation by diffusion through the pore structure. In fact some of the pore structure may be sealed. The resulting pressurization of the wasteform both in local near-surface areas and deep within the structure caused the observed spalling and complete fracture. Also, if this mechanism is correct, the effect should be less and eventually not occur at all at lower dose rates.

Using this approach, samples of 9:1 BFS/OPC (w/c=0.37) with 1.5 Molar NaOH mix water cured for 120 days prior to irradiation at 2,000 Gy h-1 were found to be damaged at between 3 and 6 MGy, and samples of 9:1 BFS/OPC (w/c=0.37) + 6 wt% HAC with 1.5 Molar NaOH mix water cured for 120 days prior to irradiation at 2000 Gy h-1 were found to be undamaged after 9 MGy. However, samples of 20 wt% IRA-420 resin in 9:1 BFS/OPC (w/c=0.37) + 6 wt% HAC with 1.5 Molar NaOH mix water cured for 120 days prior to irradiation at 2000 Gy h-1 were found to be undamaged at 2 MGy and severely damaged with surface chipping and sample splitting after 3 MGy. Samples of 20 wt% IRA-420 resin in 9:1 BFS/OPC (w/c=0.37) + 6 wt% HAC with 1.5 Molar NaOH mix water cured for greater than 120 days prior to irradiation at 200 Gy h-1 were found to be undamaged after 0.6 MGy and the irradiation will continue.

Encapsulation of Lewatit DN

Lewatit DN is a phenol formaldehyde resin used at Magnox stations for caesium removal from pond water and liquid effluents. It was one of the first waste types to be investigated and these early studies were concerned with its incorporation into pure OPC. At waste loadings of about 30% by weight (a typical target loading) the wasteform performance was satisfactory at first but over a period of several weeks the wasteform gradually expanded, and eventually became little more than a pile of crumbly lumps. A solution to this problem was found by loading the resin beads with calcium ions prior to encapsulation. However, although this worked well in the laboratory it proved difficult to make into a process because the rate at which the resin beads take up calcium ions is very slow. The move to high slag (BFS) cements led to alternative formulations which appeared to incorporate Lewatit DN without problems, although care is required not to use excessively high loadings and a relatively low water/cement ratio is essential. Such formulations have been tested over periods of up to a year and appear to give satisfactory products with respect to the expansive phase failure mechanism mentioned above.

In the expansive phase failure mechanism in pure OPC it is proposed that oxalic acid or another organic acid resulting from breakdown of the resin, leaches from the beads and interferes with the cement chemistry in a number of ways:

Enhanced precipitation of calcium hydroxide (Portlandite) in the vicinity of the resin beads.

Formation of mal-formed Portlandite crystals (massive plates rather than needle-like crystals) which are responsible for the expansive failure reaction.

Formation of crystals of other calcium salts including calcium oxalate which may be the cause of the mal-formation of the Portlandite.

Substitution of BFS for OPC alleviates this problem, and the key lies in the nature of the hydration reactions and the relative amounts of Portlandite formed. The initial products of OPC hydration are Portlandite and CaO-SiO2-H2O or C-S-H gel (which ultimately gives the product its

strength), whereas with BFS some Portlandite is consumed to generate more C-S-H gel.

Although the BFS/OPC based formulation was extensively tested with Lewatit DN and normal product evaluation data on dimensional stability, strength and other parameters obtained, there remained the question of resistance to radiation. Due to the presence of a sulfonic acid group, phenol formaldehyde type resins can give rise to the formation of expansive phases when encapsulated in some cements and exposed to g-irradiation. The mechanism is radiolytic scission of the sulfonic acid group releasing $(SO4)2-$ which then reacts with $Al2O3$ to form an expansive phase called ettringite with a solid volume increase by a factor of two. This can be overcome by reducing the $Al2O3$ content of the cement.

These difficulties with Lewatit DN resin have been addressed by using a developed formulation based upon Condensed Silica Fume (CSF) and Sulphate Resisting Portland Cement (SRPC). The $Ca(OH)2$ is removed by pozzolanic reaction with the $SiO2$ from the CSF, and both CSF and SRPC are low in $Al2O3$ thereby reducing the formation of ettringite with $(SO4)2-$ released after irradiation. However, expansive phase formation was observed when the SRPC was greater than 50 weight percent.

A 1:1 CSF/SRPC (w/c = 1) control and a 20 wt% bead Lewatit DN in 1:1 CSF/SRPC (w/c = 1.40) formulation were shown to be acceptable in terms of compressive strength, dimensional stability and underwater stability after 90 days curing. The major effect of the Lewatit is to reduce the 90 day compressive strength from 20.5 to 5.8 N mm-2. Further small scale trials have identified a maximum waste loading of between 22.5 and 25 wt% bead Lewatit DN in 1:1 CSF/SRPC, as giving acceptable values for viscosity, set time, bleed at 24 hours and underwater stability after 28 days. Reaction between the calcium and hydroxide ions and the silica framework of the CSF, results in a significant reduction in the pore water pH from 13.2 to 9.9 after 2 days and the implications of this are being addressed.

In terms of radiation stability a 1:1 CSF/SRPC control formulation was stable at a gamma dose of 2000 Gy h-1 to a total dose of 7.67 MGy, although pore water analysis has shown increased $(SO4)2-$ levels in the irradiated system. Overall the 20 wt% bead Lewatit DN in 1:1 CSF/SRPC (w/c=1.40) is found to be acceptable in terms of viscosity, set time, 24 hour bleed, compressive strength, dimensional stability, underwater stability to at least 90 days and a gamma dose of 2x103 Gy h-1 to a total dose of 9 MGy.

METHODOLOGY

Based upon the data accumulated from the above development program, some aspects going back several years, the intention now is to develop a methodology which can apply the formulations for a number of individual wastes and predict a satisfactory formulation for mixtures of wastes. Only those materials which can be anticipated from records or sampling to comprise mixtures are considered. A number of mixtures have been analyzed in this way and current work will test the resultant formulations with the simulated mixtures of wastes in the usual way.

THE STARTUP AND STATUS OF THE DOE MIXED WASTE FOCUS AREA*

J. E. Conner
U.S. Department of Energy
Idaho Operations Office

R. E. Williams
M. T. Magleby
Lockheed Martin Idaho Technologies

ABSTRACT
The Mixed Waste Focus Area began operations in February 1995. Its mission is to provide technology to support design, construction and operation of implementable treatment systems. These treatment systems shall be capable of treating DOE's mixed waste, and shall be developed in partnership with end-users and with continual input from stakeholders, tribal governments, and regulators. This paper describes the program's status at the end of its first year.
Systems Engineering has been implemented. A Complex Needs Study and the Technical Baseline, both based on site visits and the site treatment plans, have been completed. Requirements have been formalized and a program strategy has been developed. The structure and status of the program are discussed in terms of the program strategy.

INTRODUCTION

The Department of Energy (DOE) established the Mixed Waste Characterization, Treatment, and Disposal Focus Area to develop and facilitate implementation of technologies required to meet the Department's commitments for treatment of mixed low-level and transuranic wastes. The Idaho National Engineering Laboratory (INEL) has been identified as the Lead Organization for the technical management of the Mixed Waste Focus Area. A DOE Idaho Operations Office manager has overall responsibility for performance and accountability of all organization elements. Lockheed Martin Idaho Technologies is accountable to DOE-ID for the performance of each functional element. To successfully carry out the DOE's planned approach, the Mixed Waste Focus Area uses capabilities and expertise from across the DOE complex.
The mission of the Mixed Waste Focus Area is to provide technology to support design, construction and operation of implementable treatment systems. These treatment systems shall be capable of treating DOE's mixed waste, and shall be developed in partnership with end-users and with continual input from stakeholders, tribal governments, and regulators. This mission arose from the Resources Conservation and Recovery Act (RCRA) as amended by the Federal Facility Compliance Act. Each DOE site facility was required to prepare a plan for developing treatment capacities and technologies for each facility that generates or stores

mixed waste. Consent Orders have been issued for the implementation of the treatment technologies detailed in the Site Treatment Plans.

The Mixed Waste Focus Area has taken the initial approach of dividing all mixed waste streams into five waste types, based on treatability considerations: 1) waste water, 2) combustible organic, 3) homogeneous solids and soil, 4) debris, and 5) unique waste. These five waste types are used to allocate the mixed waste technology development activities within the Mixed Waste Focus Area.

REQUIREMENTS

The Mixed Waste Focus Area Proposal, written in November 1995, contains the primary set of commitments that drive the Mixed Waste Focus Area. It was analyzed for the top-level requirements that define the Mixed Waste Focus Area deliverables. These requirements are shown in Table I, and can be succinctly stated as: The Mixed Waste Focus Area shall deliver sufficient implementable technology that is correct, complete, acceptable, sponsored, permittable, safe, cost-effective, and timely such that the end-users have sufficient treatment systems to treat essentially all of the DOE Complex's mixed low-level and transuranic wastes.

Table I

STRATEGY

Top-level requirements and two higher level DOE strategy documents, the Environmental Management Strategic Plan and the EM Action Plan, were analyzed. This resulted in the identification of the following seven elements of a strategy with which to structure the MWFA Program.

1. Use a systems engineering approach,
2. Assure technical integration and implementation through Waste Type Managers,
3. Achieve program integration with a central program staff,
4. Prioritize all technology development and demonstration,
5. Assure an end-user for all technology developed or demonstrated,
6. Base technology needs on FFCA Site Treatment Plans, and,
7. Team with stakeholders, industry, and universities.

STATUS

The Status of each element of the Mixed Waste Focus Area strategy will be addressed.

Systems Engineering

Lockheed Martin Idaho Technologies has implemented systems engineering on all major programs at the Idaho National Engineering Laboratory. The systems engineering approach is evident in the development of the top-level program requirements and other aspects of the program, such as the development of the program's technical baseline.

The Systems Engineering element provides systems engineering support at the program level and through representatives on each Waste Type Team. A typical systems engineering effort consists of six basic activities, each of which are performed to support the Waste Type Teams. The six activities are requirements definition and functional analysis, alternatives development, alternatives analyses, verification and test planning, and system integration and control.

Systems Engineering personnel support each Waste Type Team in defining its systems requirements, selection criteria, and performance measurements to help ensure that all activities support the Waste Type Teams defined objectives. In addition, Systems Engineering provides systems analysis tools and techniques as needed, assist in integrating

between the Waste Type Teams, and the conduct of design reviews as appropriate.

Waste Type Managers

Five Waste Type Managers were selected from experienced leaders, proposed by the sites in the DOE Complex, through an open nomination process. The Waste Type Managers are typically from the dominant DOE site compared with needs and inventory of that specific mixed waste type. Waste Type Managers have used systems engineering processes to develop the technical baseline (Published January 1996, and discussed in more detail below, under "Prioritize all Development and Demonstration Tasks.")

Each Waste Type Manager leads a Waste Type Team dedicated to one of the five mixed waste types. The Waste Type Team consists of personnel from multiple organizations across the DOE Complex. Composition of the team is based directly on the skills needed, including technical, legal, regulatory, stakeholder, and systems engineering. The team makeup is dynamic, while the team leadership is maintained constant for consistency and stability.

Members of a Waste Type Team are expected collectively to: a) be fully knowledgeable of waste, including inventories, within the specific waste type, b) understand the customer (EM-30, EM-40, and EM-60) plans for managing that waste, c) be knowledgeable of ongoing and proposed technology development activities that could apply to the specific waste type, and, d) understand the risks associated with their target wastes.

DOE customer needs are a necessary input to the work of the Waste Type Teams. To define the deficiencies or needs of the DOE Environmental Management customers, the Mixed Waste Focus Area analyzed Proposed Site Treatment Plans, and other applicable documents, and conducted site visits throughout the summer of 1995. Representatives from the Office of Waste Management (EM-30), the Office of Environmental Restoration (EM-40), and the Office of Facility Transition and Management (EM-60) at each site visited were consulted to collaboratively define their technology needs. These needs were categorized by the five mixed waste types.

The site visits had several specific purposes: 1) to identify the technology development needs for managing mixed wastes at the DOE sites; 2) to understand the regulatory status/situation at the sites; 3) to status the technology transfer and other privatization efforts at the sites; 4) to identify completed, ongoing, and planned technology development work being conducted by EM-30, 40, 50, and 60 at the sites; and, 5) to identify potential matches between current capabilities and defined site technology needs or "quick wins."

Prioritize all Development and Demonstration Tasks

One of the first products of the Waste Type Teams was a prioritized, defensible technical baseline. The technical baseline is based on the Complex needs for waste treatment systems, and the technologies needed to make those systems implementable. It forms the basis for deciding which technology development activities will be supported by the Mixed Waste Focus Area. The technical baseline forces a strong technical justification for funding technology development. Technology development activities are tied to customer needs and systematically integrated with other development activities. Development of technologies is supported only when they are not commercially available. Development of the technical baseline is further described in more detail in a companion paper.

Program Organization

Organizationally, the Mixed Waste Focus Area includes the following functional units: Technology Coordination, Technical Resource Team, Waste Type Team, Waste Type Manager, Regulatory and External Liaison Program, Program Integration, and Systems Engineering. Waste Type Team members report to a Waste Type Manager. Waste Type Managers programmatically report to the Manager of Technology Coordination as does the Technical Resource Team, completing the integration cycle.

Regulatory and External Liaison, Waste Type Teams, Waste Type Mangers, and Systems Engineering are discussed separately in this paper.

The primary function of Technology Coordination is to participate on the Waste Type Team to coordinate technology development and to facilitate implementation of technologies for mixed waste.

The Technical Resource Team consists of science and engineering experts in waste management disciplines including technology development, characterization, thermal treatment, solidification and stabilization, decontamination, waste handling, and disposal. The Technical Resource Team supports the Waste Type Teams by: 1) evaluating existing, new and proposed technology development activities; 2) providing the technical input to directed calls for proposals to fill technology deficiencies; 3) evaluating proposals and recommending preferred technology solutions; 4) coordinating technical support that crosscuts the Waste Type Teams; and, 5) assisting in the selection of a preferred waste type technical strategy.

The Program Integration and Control element implements and maintains a sound program management process within the Mixed Waste Focus Area. This element provides project cost and schedule planning and control, and document management to the Mixed Waste Focus Area. Program Integration coordinates activities and interests with the other Focus Areas, the Crosscutting Technology Programs, and the Technology Task Plan Principal Investigators. The Mixed Waste Focus Area Program Integration Function handles all formal call letters and conducts the formal transactions leading to approval and changes to the Technology Task Plans with input from the Waste Type Teams.

End-user

The Mixed Waste Focus Area strategy calls for closely working with potential end-users of the technologies being developed. The key objective of this strategy element is to avoid a previous mistake - developing technologies that no one wants. The Waste Type Managers were selected from EM-30 programs specifically to improve the chances that the technology development would "hear the voice" of the end-users. When they came on board, Technology Coordination and the Waste Type Managers conducted site visits to listen to the needs of the end-users. The program is committed to fund only those technology development and demonstration tasks for which an end-user can be identified.

Federal Facility Compliance Act Site Treatment Plan Basis

Federal Facility Compliance Act Site Treatment Plans are key technical drivers of the program. Prioritization is based on waste volumes identified in the Site Treatment Plans. Treatment train and technology deficiency identification begin with a search of the Mixed Waste Inventory Report compiled as a component of the Site Treatment Plans. The achievement of the Level 1 requirements "correct" and "timely" will be based on the waste streams identified, and schedules negotiated and agreed-upon through the Site Treatment Plan process, respectively.

Teaming

In the past four years there has been increasingly greater emphasis placed by DOE on mutually beneficial relationships with industries, universities, tribal governments and the public. The Mixed Waste Focus Area has a strong commitment to assure that all possible teaming arrangements are considered and employed where possible.

To support this strategy element, an efficient regulatory and external liaison system has been established. To ensure success, the Mixed Waste Focus Area is initiating a variety of regulatory and external liaison activities. The Regulatory and External Liaison program element helps Waste Type Teams to acquire regulatory, industry, university, and stakeholder input. This input helps define needs, address regulatory options, provide early involvement of stakeholders in product development. It also supports technology selection, prioritization, and evaluation.

CONCLUSION

The Mixed Waste Focus Area has been organized and is operating. Waste Type Managers representing sites with the major mixed waste inventories and/or problems have the charter to provide the primary direction of the technology development and demonstration tasks. Systems engineering methods have played an important part in the preparation of the initial documents and planning processes. A technical baseline was developed and forms the basis of the Fiscal Year 1997 budget submittal. The program has a strong and active Regulatory and External Liaison Unit dedicated to ensuring stakeholder input and ultimately gain their acceptance.

12-2

MIXED WASTE CHARACTERIZATION, TREATMENT, AND DISPOSAL FOCUS AREA TECHNICAL BASELINE DEVELOPMENT PROCESS

Dirk Gombert
Steve Priebe
Jay Roach
Lockheed Martin Idaho Technologies

ABSTRACT

The U. S. Department of Energy (DOE) created the Mixed Waste Characterization, Treatment, and Disposal Focus Area (MWFA) to develop and facilitate implementation of technologies required to meet its commitments for treatment of mixed wastes under the Federal Facility Compliance Act (FFCA), and in accordance with the Land Disposal Restrictions (LDR) of the Resource Conservation and Recovery Act (RCRA). Mixed wastes include both mixed low-level waste (MLLW) and mixed transuranic (MTRU) waste.

The goal of the MWFA is to develop mixed waste treatment systems to the point of implementation by the EM customer. To accomplish this goal, the MWFA is utilizing a three step process. First, the treatment system technology deficiencies were identified and categorized. Then these identified needs were prioritized. This resulted in a list of technical deficiencies that will be used to develop a technical baseline. The third step, the Technical Baseline Development Process, is currently ongoing. When finalized, the technical baseline will integrate the requirements associated with the identified needs into the planned and ongoing environmental research and technology development activities supported by the MWFA.

Completion of this three-step process will result in a comprehensive technology development program that addresses customer identified and

prioritized needs. The MWFA technical baseline will be a cost-effective, technically-defensible tool for addressing and resolving DOE's mixed waste problems.

INTRODUCTION

The Assistant Secretary for the Office of Environmental Management (EM) at the United States Department of Energy (DOE) initiated a new approach in August of 1993 to environmental research and technology development (1). The key features of this new approach included establishment of five "focus areas" and three "crosscutting technology" programs, which overlap the boundaries of the focus areas. The five focus areas include the Contaminant Plumes Containment and Remediation; Mixed Waste Characterization, Treatment, and Disposal; High-Level Waste Tank Remediation, Landfill Stabilization, and Decontamination and Decommissioning Focus Areas. The three crosscutting technologies programs include Characterization, Monitoring, and Sensor Technology; Efficient Separations and Processing; and Robotics. In addition, an Industrial Programs group has been established to support all of the focus areas and crosscutting programs. The major characteristic of the new approach is that aggressive teaming with the customers within EM, through the focus areas, is used to identify, develop, and implement needed technologies such that the major environmental management problems can be addressed, while cost-effectively expending the funding resources.

APPROACH OF THE MIXED WASTE FOCUS AREA

The DOE created the Mixed Waste Characterization, Treatment, and Disposal Focus Area (MWFA) to develop and facilitate implementation of technologies required to meet its commitments for treatment of mixed wastes under the Federal Facility Compliance Act (FFCA), and in accordance with the Land Disposal Restrictions (LDR) of the Resource Conservation and Recovery Act (RCRA). Mixed wastes include both mixed low-level waste (MLLW) and mixed transuranic (MTRU) waste. Mixed low-level waste is defined as waste that contains both hazardous constituents, as identified by RCRA, and radioactive constituents, including alpha-emitting radionuclides below concentrations of 100 nanoCuries per gram. Mixed transuranic waste contains RCRA and radioactive contaminants, including alpha-emitting radionuclides with concentrations greater than or equal to 100 nanoCuries per gram. This mixed waste only includes those materials that have an atomic weight greater than 92, or a half-life greater than 20 years.

The goal of the MWFA is to develop mixed waste treatment systems to the point of implementation by the EM customer. To accomplish this goal, the MWFA is utilizing a three step process. First, the treatment system technology deficiencies were identified and categorized. Then these identified needs were prioritized. This resulted in a list of technical deficiencies that will be used to develop a technical baseline. The third step, the Technical Baseline Development Process, is currently ongoing. When finalized, the technical baseline will integrate the requirements associated with the identified needs into the planned and ongoing environmental research and technology development activities supported by the MWFA. The following sections describe these steps.

Needs Identification and Categorization Process

To define the deficiencies or needs of the EM customers, the MWFA used two mechanisms: site visits and process flow/treatment train development. The MWFA completed the site visits throughout the summer of 1995. Prior to conducting each site visit, the MWFA analyzed Proposed Site Treatment

Plans (2) (PSTPs), or similar documents, to perform an initial assessment of the technology deficiencies at that site. Site representatives from the Office of Waste Management (EM-30), the Office of Environmental Restoration (EM-40), and the Office of Facility Transition and Management (EM-60) were requested to consult with the MWFA to further define their technology needs. Personnel from these programs participated in the MWFA site visit as deemed appropriate by the respective sites.

The site visits had several specific purposes

1) to identify the technology development needs for managing mixed wastes at the DOE sites;
2) to understand the regulatory status/situation at the sites;
3) to status the technology transfer and other privatization efforts at the sites;
4) to identify completed, ongoing, and planned technology development work being conducted by the sites;
5) to identify potential matches between current capabilities and defined site technology needs, which could expedite implementation of a technology for treating actual mixed waste (referred to hereafter as "quick wins").

The data provided in the PSTPs was analyzed according to waste type to determine the sites that have the largest volumetric inventory for each category. The waste type categories, namely Wastewater, Combustible Organic, Homogeneous Solids/Sludges/Soil, Debris/Solid, and Unique Wastes, are defined below. As a result of this analysis, the following DOE facilities were identified for site visits:

1) Idaho National Engineering Laboratory (INEL),
2) Savannah River Site (SRS),
3) Hanford Reservation (Hanford),
4) Oak Ridge Reservation (ORR), 5) Ohio Sites (Ohio),
5) Rocky Flats Environmental Technology Site (RFETS),
6) Albuquerque Sites (AL).

The data generated for this evaluation is available upon request. Based on the information reported in the PSTPs, the MWFA effectively addressed the technology needs for over 80% of the DOE mixed waste inventory through the site visits.

As previously mentioned, the needs identified during the site visits were categorized by Wastewater, Combustible Organic, Homogeneous Solids/Sludges/Soil, Debris/Solid, and Unique waste types. These waste types are defined as follows:

Wastewater waste streams, which comprise approximately 3% of the total DOE Complex mixed waste inventory, include liquids and slurries. Slurries are defined as liquids with a total suspended solids (TSS) content greater than 1% and less than 30%. Liquids and slurries defined as Wastewaters contain less than 1% total organic carbon (TOC).

Combustible Organic waste streams, which comprise approximately 1.5% of the total DOE Complex mixed waste inventory, include liquids and slurries containing greater than 1% TOC, and solids with a base structure that is primarily organic such that a maximum of approximately 20% by weight would remain as residue following incineration. Solids are defined, including sludges, as having greater than 30% TSS.

Homogeneous Solids/Sludges/Soil waste streams, which comprise approximately 48% of the total DOE Complex mixed waste inventory, include waste that is at least 50% by volume inorganic sludges, including water content. Sludges are defined as having a TSS greater than 30%. A sludge

may be a mixture with a stabilization agent that has not properly solidified, or may be a mixture with absorbent materials. This category also includes inorganic particulate, paint waste, and salt waste.
Debris/Solid waste streams, which comprise approximately 46% of the total DOE Complex mixed waste inventory, include waste that is at least 50% by volume materials that meet the EPA LDR criteria for classification as debris (..."material exceeding a 60 mm particle size that is intended for disposal...") This category also includes waste that is estimated to be 50% by volume soil, including sand or silt, rock, or gravel which does not meet the EPA LDR criteria for debris.
Unique Wastes, which comprise approximately 1.5% of the total DOE Complex mixed waste inventory, generally include low volume waste streams such as elemental heavy metals, batteries, reactive metals, explosives, compressed gases, lab packs, and other miscellaneous wastes that present unique treatment problems and are not included in the previously defined categories. It also includes the Final Waste Form and Unknown/Other category wastes [Z and U series waste streams identified in the DOE Waste Treatability Group Guidance (3) document, (DOE/LLW-217), January 1995].
The needs identified by the DOE Complex during the site visits were compiled and documented in the Mixed Waste Focus Area Department of Energy Technology Development Needs Report (Needs Report), November 1995 (INEL-95/0555) (4). Several categories of needs and deficiencies are identified in the Needs Report. These deficiencies and technology gaps are broadly categorized as waste type specific and general, non-waste type specific needs. The waste type specific needs are further categorized as general and site specific needs. The non-waste type specific deficiencies and needs are grouped as waste characterization, container integrity, waste handling, treatment system, and programmatic needs. Over 70 specific needs were identified through the site visits and the information obtained from the PSTPs and other applicable documents.
The MWFA selected Waste Type Managers (WTMs) from across the DOE complex to help resolve the site needs related to each of the five waste types. These individuals were selected from experienced leaders, proposed by the sites in the DOE Complex, through an open nomination process. Their primary responsibility is to ensure that the required technologies are available to allow the EM customers to eventually bring the mixed waste inventories associated with each waste type into full regulatory compliance. For this reason, the MWFA chose WTMs for each waste type with a broad experience base in the specific waste category, as well as an EM background. The insight, complex-wide contacts, and knowledge that these individuals provide are necessary resources to ensure that the needs identified by the sites are integrated into the technical baseline and effectively addressed.
In addition to the needs identified during the site visits, other technology deficiencies were defined. These deficiencies were related to the treatment process flows and treatment trains developed for the DOE complex mixed waste inventory. Treatment process flows and associated treatment trains were defined by the MWFA. These treatment process flows address every mixed waste stream identified in the PSTPs. The treatment process flows were generated based on the preferred treatment options identified by the sites in the PSTPs, in conjunction with the process flow diagrams that had been generated during development of the DOE Programmatic Environmental Impact Statement (PEIS). The primary resource documents for this data were the Mixed Waste Treatment Model: Basis and

Analysis (5), September 1995 (LA-13041-MS), and Analysis of Waste Treatment Requirements for DOE Mixed Wastes (6), February 1995 (BCMusgrave Inc., Livermore, CA).

The WTMs, with support from the MWFA Technical Resource Team (TRT), developed an initial list of the technology gaps associated with the process flow diagrams that were defined for the respective waste types. These needs were identified based on the technologies included in the treatment trains associated with the treatment process flow diagrams developed by the WTMs. The technology gaps identified by the WTMs and the TRT were then compared to the needs and deficiencies listed in the Needs Report.

Although over 70 needs were initially identified, only 30 were considered for evaluation in the MWFA Technical Baseline Prioritization Process. This reduction was due to several factors. Some of the needs were identified for more than one waste type, which resulted in duplications. These were combined into one overall need statement. Other needs identified were very site specific, and not generally applicable to a significant volume of waste within a waste type. These deficiencies were removed from consideration in this prioritization process. However, they will be considered on a case-by-case basis as potential quick wins, as discussed below. Some of the remaining deficiencies listed in the Needs Report are clearly more applicable to other focus areas and/or crosscutting programs. The boundaries of responsibility between the five focus areas are presently being defined by the respective program leads. Finally, some of the deficiencies included in the Needs Report were programmatic in nature or related to MWFA policy definition. The prioritization process was not applicable to these types of needs, since it was developed to perform technical evaluation of deficiencies.

Needs Prioritization Process

After the initial evaluation and disposition of the identified technology gaps and deficiencies, the remaining needs were generalized and rolled up into 30 deficiency categories. These 30 "needs" were then prioritized using a three-phase evaluation process. Phase I of the process included prioritization of treatment process flows. Phase II included prioritization of the technology deficiencies and needs associated with these process flows. Phase III integrated the separate prioritization processes completed in the first two phases to develop a final prioritized list of needs associated with the defined treatment process flows.

Both quantitative and qualitative criteria were used to evaluate the treatment process flows and technology deficiencies. The set of criteria used to prioritize process flows was not the same as the criteria used to prioritize the deficiencies. In addition, each criteria was weighted based on its relative importance within the prioritization framework. The criteria and respective weight and scale of merit were developed by the WTMs and TRT. The three phase prioritization process is described in detail, below.

Phase I of the prioritization process used by the MWFA included prioritization of the identified treatment process flows. As previously stated, treatment process flows were developed for every DOE mixed waste stream based on the data contained in the PSTPs and the PEIS. Process flows were included in the prioritization only if a technical deficiency had been identified for that process flow. As a result, 17 treatment process flows were prioritized in Phase I. The evaluation was based on

quantitative and qualitative criteria. Each criteria was assigned an individual weighting, as well as a defined scale of merit. The criteria, weight, and scale of merit used to prioritize the treatment flow processes are presented in Table I.
Table I
The resulting prioritization of the treatment process flows is shown in Table II.
Table II
Phase II of the MWFA prioritization process involved ranking of the identified technical deficiencies These needs had been defined during the site visits and by the WTMs, as related to the treatment process flows. Prioritization of the technical deficiencies was performed based on a different set of criteria than that used to rank the treatment process flows in Phase I. The criteria were both quantitative and qualitative, as before, but the specific criteria were different. These criteria, along with the associated weight and scale of merit, are listed in Table III.
Table III
Phase III was the final, and most difficult, step of the MWFA Needs Prioritization Process. Phase III involved combining the separate prioritization of technology needs and treatment process flows into a single, integrated prioritization. Several methods for combining these independent prioritization were considered. Some techniques were quantitative, such as multiplying technical deficiency scores by the applicable process flow scores. Other methods were qualitative, such as using a graphical approach to determine the highest frequency for combinations of high priority process flows and deficiencies.
The latter method was chosen because a legitimate statistical method for mathematically determining a score could not be identified that did not give double credit for applicability to multiple treatment process flows. Consequently, the final integrated prioritization was accomplished by constructing a matrix with the 17 prioritized process flows listed horizontally across the top and the 30 prioritized deficiencies listed vertically down the left side. The matrix was then quartered, with the upper left portion given highest priority (high-highs), followed by the lower left portion, then the upper right portion, with the lowest priority section being the lower right portion (low-lows). This order was based on the opinion of the WTMs that the ranking of the treatment process flows (Phase I) had priority over the individual technology deficiency ranking (Phase II). The deficiencies were then prioritized according to their frequency within each quarter, and the priority of each quarter. This lead to a final, integrated prioritization for the deficiencies identified for the DOE mixed waste inventory, as shown in Table IV.
Table IVa
Table IV, cont.
Table IV, cont.
Technical Baseline Development Process
The term "technical baseline" refers to the recommended list of technology development activities that the MWFA will support to resolve the needs identified related to DOE Complex mixed waste. The activities included in the technical baseline will address the highest priority deficiencies, based on the results of the prioritization process.
The needs identification, categorization, and prioritization recently completed by the MWFA constitutes the first phase of the Technical

Baseline Development Process. This phase has been documented in detail in the Mixed Waste Focus Area Integrated Technical Baseline Report Phase I - Volume I and II (7), (DOE/ID-10524, January 16, 1996). The next step, which is in progress, involves issuance of directed calls for proposals within DOE and Requests For Proposals (RFPs) to industry and academia. The prioritized needs and technology deficiencies will be used by the WTMs as the framework for developing these directed calls and RFPs.

To make the directed calls for proposals and RFPs as effective as possible, the MWFA has recently issued a Request For Information (RFI) to industry and academia. This RFI will be used to determine the expertise that exists outside of the DOE complex related to the technical deficiencies that have been identified. The content in the subsequent RFPs and directed calls will be based on evaluation of the responses to the RFI. DOE deficiencies related to technology areas that seem more suited to industry and/or academia will be included in the RFPs. Other technical deficiencies will be addressed to the DOE complex through directed calls. The calls and RFPs issued for FY-1997 will be focused on the top priority deficiencies identified for the DOE complex. The technical task plans (TTPs) and industry/academia proposals that are received in response to these calls and RFPs will then be prioritized.

Prioritization of the individual TTPs and proposals that will eventually constitute the technical baseline is a multiple tiered process. The priority of the TTP or proposal is based not only on the technical merits of the proposed work, but also on the priority of the "need" that it addresses. The priority of the "need", as previously defined, is based on the priority of the treatment process flow system or systems that it is associated with, as well as the priority of the deficiency itself. The MWFA TRT, in conjunction with the WTMs, is currently finalizing the prioritization system necessary to evaluate TTPs and proposals. The evaluation criteria, and associated weightings and scales of merit, will be similar to those used to evaluate the specific technical deficiencies.

The results of the evaluation and prioritization of TTPs and proposals will constitute the MWFA technical baseline. However, the DOE system is very dynamic and constantly changing. Accordingly, the technical baseline will be evaluated semi-annually, and the supporting projects will be reviewed quarterly to ensure that the EM customer priority needs are being met in an effective manner. As the situation in the DOE complex mandates changes to the technical baseline, the WTMs will use subsequent directed calls and RFPs to address new/different needs. The prioritization system developed will be used to evaluate the TTPs and proposals that are submitted in response to these calls to ensure that the work supported by the MWFA is directly addressing the highest priority customer needs.

Quick Wins Disposition

As previously stated, quick wins, as well as identified needs with characteristics similar to quick wins, were not considered in the MWFA Needs Prioritization Process. As a result, these activities are not part of the ongoing Technical Baseline Development Process. This is because these activities are usually site specific and address small waste volume problems. A broad range of activities may be classified as quick wins, but these can generally be categorized into the following four areas.

1. Tasks that provide opportunities to transfer technologies between sites, resulting in expedited treatment schedules and/or reduced costs.

2. Tasks that provide for expedited treatment of actual mixed wastes through RCRA treatability studies, preferably eliminating the target waste stream at the treatment site.
3. Tasks that resolve regulatory issues, allowing expedited treatment of mixed waste.
4. Tasks that provide for more efficient utilization of existing equipment and capabilities within the DOE complex in treating mixed waste.

Presently, almost 30 quick win opportunities have been identified, and additional quick wins will most likely be defined as the WTMs continue to further analyze their respective waste streams. A modified form of the evaluation process and criteria utilized to prioritize the DOE Complex mixed waste needs has been finalized by the WTMs. An internal call for proposals is expected to be distributed to the sites during the first quarter of CY-1996. A set funding level has been established specifically for addressing quick wins, and as the quick wins are prioritized, the available budget will determine the activities that are supported by the MWFA.

CONCLUSION

The initial DOE complex needs identification, categorization, and prioritization is an excellent step toward resolving the needs of the EM customers. The information collected to date is recognized as the first phase in development of an implementable technical baseline. Completion of the initial MWFA Technical Baseline will be accomplished in the ensuing months.

The quarterly and semi-annual reviews of the MWFA program will ensure that the customer needs are identified, addressed, and eventually resolved. In addition, these reviews will ensure that the technical baseline is continually updated and properly documented.

The use of directed calls for proposals and RFPs, which is a departure from the historical approach of issuing general calls for proposals, is seen as one of the most beneficial tools that the MWFA will use. Technically specific calls for proposals will be issued that are directed at resolving particular customer needs. This process is so beneficial because it allows the MWFA to consistently make comparative evaluations of proposals, ensuring that the prioritization process produces the most efficient, cost-effective, timely decisions. The end result will be a technically defensible, documented baseline that is guaranteed to meet the EM customer needs, as they are understood at the time of evaluation.

ABSTRACT

The U.S. Department of Energy (DOE) has undertaken a study of Integrated Nonthermal Treatment Systems (INTS) for mixed low level waste to assess the present state of technology and to identify research and development requirements for implementation. For the purposes of this study, nonthermal is defined as processes operating below 660F. Flowsheets and conceptual designs were developed for five systems treating a representative spectrum of mixed waste. Mass balances were performed, residual volumes calculated, and total life cycle costs estimated for each system. This study is patterned after a recently published study of Integrated Thermal Treatment Systems (ITTS). This paper describes the nonthermal systems and preliminary results of the INTS study.

INTRODUCTION

The mixed low level waste in the DOE complex consists of a variety of organic and inorganic solids and liquids contaminated with hazardous and radioactive substances. These waste streams include aqueous and organic liquids, soils, organic and inorganic sludges, and combustible and non-combustible debris. Mixed wastes containing hazardous organic compounds, which are typically treated by thermal technologies, are a particular problem due to the current difficulty of permitting and siting incinerators. Although incineration is the Environmental Protection Agency (EPA) best demonstrated available technology for many organically-contaminated wastes and it can treat a wide variety of wastes, there is a lack of public acceptance due to potential emissions of toxic metals and products of incomplete combustion (1).

These issues associated with incineration, and the need expressed by stakeholders for information on nonthermal systems to allow informed decisions on waste treatment options (2), prompted DOE to initiate the Integrated Nonthermal Treatment Systems study. Five nonthermal treatment systems were studied which included the following technology categories: washing, thermal desorption, organic destruction by chemical processes, aqueous waste and offgas treatment, and waste stabilization. The purpose of this study was to evaluate the potential for treating the DOE mixed waste by nonthermal processes, identify research and development requirements, and to compare these systems to each other with respect to performance, effluent production and disposal volume, and life cycle cost. To allow a subsequent comparison with thermal systems previously studied, the same assumptions and waste profile were used for the INTS study as were used in the earlier ITTS study (3).

For these studies, nonthermal is defined as less than 660F, which is below the temperature at which dioxins are thought to form in an offgas stream and below the temperature at which most metals will volatilize (mercury being the exception). Integrated systems include all facilities required to treat the defined waste streams from the time they enter the facility through disposal. This includes administrative and laboratory support, material handling, separation and destruction of organic materials, immobilization of inorganic materials, treatment of residue to comply with appropriate regulations, and disposal.

The goals for the treatment systems are to remove organic contaminants from the solid matrices, destroy the separated and stored organic material, and stabilize the inorganic contaminants with the solid matrices to meet the Toxicity Characteristic Leaching Procedure tests prior to disposal. The organic contaminants must be removed and/or destroyed to the Universal Treatment Standards to meet the EPA land disposal restrictions. The inorganic contaminants may be removed during the washing or organic destruction processes, and therefore contribute to the secondary waste stream as precipitated heavy metals or radionuclides. This paper briefly describes the systems and technologies that were evaluated as part of the nonthermal studies, the waste stream configuration entering the systems, and the partitioning of the wastes to the various treatment processes. The results of the study are presented in terms of effluent, waste requiring disposal, and cost. It should be pointed out that these analyses are based on preconceptual design concepts, and very limited relevant performance data. A considerable research and development effort will be required before such systems could be considered for implementation for the treatment of DOE mixed waste.

WASTE STREAM DESCRIPTION

The waste profile shown in Fig. 1 represents an average composition of wastes from the 20 largest DOE sites (excluding the Hanford tank waste and Rocky Flats pondcrete), which is about 99% of the stored waste in the complex. These data were extracted from the Interim Mixed Waste Inventory Report (IMWIR) (4) and used in the ITTS and INTS studies. Although the IMWIR data have been updated several times since the ITTS study was performed, the older IMWIR data were used in the INTS study to allow a valid comparison between the two studies. The same waste profile was used for each system, and each system was sized to treat 2927 lbs/hr.a In addition to the waste streams identified in Fig. 1, salts comprised 0.3% of the total, and lead and mercury comprised 1%. The wastes are sorted at

the front end of each treatment system and routed to the appropriate treatment process as shown in Table I.

Fig. 1

Table I

In the following discussion, soft debris is defined as combustible debris (e.g., wood, paper, rags, plastic, etc.), open debris consists of items with easily accessible surfaces that can be decontaminated (e.g., sheet metal, bricks, concrete, rocks, rubble, etc.), and complex debris is defined as items such as pumps, valves, and motors that have internal surfaces that trap contaminants and cannot be easily accessed for decontamination, and that are difficult to shred or break open. Complex debris is a small part of the total waste stream.

TREATMENT SYSTEMS

A summary of the systems evaluated is provided as Table I. In comparison to thermal systems, the waste entering the facility requires extensive characterization, sorting, and size reduction because nonthermal treatment processes are not as versatile or robust as thermal processes. Size reduction requirements will vary depending on the waste matrix and the method of treatment. For example, solidified inorganic sludge will require extensive size reduction to allow access to the organic contaminants trapped within the solidified matrix. Debris may require little or no size reduction, or extensive size reduction, depending on the type of debris and method of treatment.

Bulk metal may be separated from the general category of debris for size reduction, decontamination, and storage for subsequent recycle. Thus, complex bulk metal debris with internal contamination may be recycled, or macroencapsulated in grout without treatment. Other bulk metal items with surface contamination (metal drums, lead bricks, sheet metal, etc.) will be decontaminated and recycled. Lead blankets and lead gloves will be macroencapsulated in polymer in accordance with EPA's debris rule. There are also some debris items that cannot be decontaminated, e.g. highly deteriorated drums and firebrick, which may contain radionuclides but no organic contaminants. Such items will be grouted without treatment. As with the ITTS study, bulk contaminated metallic mercury that can be sorted from the waste stream is amalgamated, and funds have been allocated for treating special wastes, but no specific treatment methods are identified.

All systems use a gas phase corona reactor (GPCR) to destroy trace levels of volatile organic contaminants in the offgas streams (5). The GPCR consists of a cylindrical ceramic or glass reactor. When a high voltage alternating electric field is established across the gap between concentric electrodes separated by dielectric beads, corona discharges occur between the beads creating a plasma that decomposes the organic contaminants in the gas flowing through the reactor.

The quantity 2927 lb/hr is based on a nominal hourly throughput of 2000 lb "combustible" waste, as defined by the ITTS study. The additional 927 lb/hr includes all other waste streams and materials associated with the waste, including metal drums, lead, mercury, aqueous waste, and special wastes (requiring as yet unspecified "special" handling).

Ultraviolet (UV) photooxidation (6), a relatively common and commercialized process, is used in all five systems to destroy organic contaminants in the aqueous waste. Organic compounds are destroyed through an indirect photochemical process that uses UV energy to generate hydroxyl radicals from either hydrogen peroxide or ozone in the bulk

fluid. These radicals oxidize the organic species in the water. Pretreatment of the waste stream is required for proper functioning of the system and to minimize down time and maintenance requirements. This includes removal of suspended solids and immiscible organics to allow penetration of UV light into the wastewater, removal of dissolved solids that may produce scale on the UV lamps or windows, and removal of hydroxyl scavengers that diminish the ability of the system to destroy the organic contaminants.

System #1 - Grout Debris

In System #1, all debris are stabilized in grout without treatment to comply with the EPA debris rule. This is similar to the process proposed in many of the DOE site treatment plans.

Soils and inorganic sludges are treated in a vacuum desorber (7) to thermally desorb high boiling point organics, such as PCBs. Thermal desorption may also remove volatile metals, such as mercury, and volatile metal compounds; however, a process for solubilizing mercury or mercury compounds is included after the desorption step to remove incompletely volatilized mercury compounds. The mercury-contaminated matrix is mixed with a solution of potassium iodide and free iodine (8), and the solids drained and washed with water. A soluble mercury/iodine complex is formed and the wash solution containing the complex is reacted with zinc or iron to precipitate mercury metal and form an amalgam to stabilize the mercury.

Desorbed organics that are condensed in the offgas treatment system, stored organic liquids, and organic sludges are destroyed using a silver-based mediated electrochemical oxidation (MEO) process (9). Several MEO processes are being developed; however, the process evaluated in these studies uses Ag(II) as the oxidizer in a supporting electrolyte of HNO3 at ambient pressure and near ambient temperature. The oxidizer is reduced in these reactions, is regenerated (oxidized) at the anode of an electrochemical cell, and then migrates back into the bulk electrolyte to oxidize the organic compounds. Although Ag(I) forms insoluble AgCl in the presence of halide anions generated during the destruction of halogenated organics, a process has been identified to recover and recycle up to 99.9% of the silver from the AgCl precipitate (9). The principal cathode reaction is the reduction of nitric acid to nitrous acid, which is reacted with oxygen to regenerate nitric acid.

The treated soil is stabilized in grout, and the treated sludge is stabilized in polymer. Secondary salt residue resulting from precipitation of dissolved solids from aqueous waste, the MEO process, or neutralization of acid gases are polymer stabilized.

System #2 - Thermal Desorption

System #2, and all the following systems, involve enhanced debris treatment wherein the debris is treated to remove organic contaminants before stabilization and disposal. In this system all the debris, soil, and inorganic sludge are thermally desorbed using a batch vacuum system, and mercury is removed using the KI/I2 process. Temperatures less than 250F are required when desorbing soft debris to prevent melting of plastics and excessive offgassing of the organic debris matrix. Complex debris is reduced in size to allow access to internal surfaces. The MEO process of System #1 is replaced with a catalytic wet oxidation (CWO) (10) process to treat organic liquids and organic sludges .

The CWO process uses Fe(III) in a hydrochloric acid solution to oxidize waste organics while solvating heavy and/or radioactive metals. Catalysts

increase the oxidation rate for organics, and Fe(II) formed in the oxidation process is oxidized back to Fe(III) by a second catalyzed reaction with oxygen. The process typically takes place at 212-570F, and at pressures of 20-200 psig, depending on the waste feed and composition. The residual solids are filtered from the solution, rinsed, and polymer stabilized for disposal. The reagent is recovered and recycled.

System #3 - Washing

For all solid waste matrices, System #3 uses aqueous washing with selected surfactants or other additives to solubilize and remove organic contaminants; in the process some of the inorganic contaminants are removed as well. As in System #2, complex debris is size reduced to allow access to internal surfaces. An agitation wash process, similar to that used in typical radiation facility laundry, is used for soft debris to prevent rags, paper, etc. from sticking together. A high pressure spray wash (11) is used for shredded complex and open debris, and a soil washing process is used for soils and inorganic sludges (12). The MEO process is used to treat organic liquids and organic sludges. Surfactants are recovered and the treated wastewater recycled back to the washing process to minimize consumptive use of water.

System #4 - Combination with Acid Digestion

Phosphoric/nitric acid digestion (13) is used to decompose combustible/soft debris to decrease the volume of waste sent to disposal, and to treat organic liquids and organic sludges. Complex debris is grouted without treatment, thereby eliminating the need for extensive size reduction, and grout is used to stabilize treated open debris. High pressure spray wash is used to decontaminate open debris, and aqueous soil washing is used to remove organic contaminants from the soil matrix. Vacuum thermal desorption is used to treat inorganic sludges and mercury is removed using the KI/I2 process. Phosphate-bonded ceramics (14) are used to stabilize soils, inorganic sludges, and insoluble salts and oxides, and polymer is used to stabilize soluble salts.

As with all chemical destruction processes, acid digestion requires shredding of soft debris because of the strong surface area dependence of the dissolution and reaction rates. Many organic materials are completely oxidized at atmospheric pressure and below 350F; however, decomposition of more stable compounds may require conditions in the range of 390F and 15 psig. As the reaction progresses, NO and NO2 are released from solution and recovered as nitric acid. Upon cooling the solution, heavy metals and radionuclides will precipitate as highly insoluble phosphates or oxides.

System #5 - Combination with Chemical Wet Oxidation

This system is identical in design to System #4 except that chemical wet oxidation replaces phosphoric/nitric acid digestion, and polymer and grout stabilization replace phosphate-bonded ceramics.

STUDY RESULTS

The results of the study include an estimate of the system effluent (gas, liquid, and solid) and costs. The ASPEN PLUS computer code (15) was used to model each unit operation and simulate the process for each system. Simplifying assumptions are used to combine several unit operations, where appropriate. The code solves for equilibrium chemistry using Gibbs energy minimization techniques, or uses experimental data if available for reactions, but no kinetics are considered. All mass (waste, chemical reagents, air, water, etc.) is accounted for in the calculations, and the mass output from each system equals the input. The output volume is used

in the cost calculations to assess the cost of disposal, and the sizes of process units used in the cost analysis are based on throughput data obtained from the technology developers.

Effluent

The discharge rates of gas, liquid, and solid effluent from the five systems are shown in Fig. 2. The volumetric discharge rates (shown in Fig. 3) of solid waste forms sent to disposal are lowest for systems (#4 and #5) in which soft (combustible) debris is decomposed and is, therefore, not part of the solid waste leaving the systems. However, the difference is small (approximately 1600 lbs/hr or 10 ft3/hr). The ratio between input and output waste volumes varies between 1.02 and 0.80; however, these calculations are based on an assumed waste density for the input waste (64 lbs/ft3) that may vary by a factor of two depending on packing density of the as received containers.

It is assumed that the wastewater is treated and recycled to minimize consumptive use; however, these systems generate more water than is required, so that there is some discharge. As seen in Fig. 2, this discharge is similar for all systems and is approximately 1000 lbs/hr (1.4 gpm) or less. As expected, the gaseous effluent from these systems is relatively small and consists primarily of CO2 from the destruction of organics. Because combustible debris is destroyed in Systems #4 and #5, the offgas from these systems is higher than from the other systems in which all debris is stabilized as solid waste. The higher offgas from the desorption system (#2) compared to system #1 is due to volatilization of the organic constituents of the soft debris, which are subsequently condensed and oxidized.

Cost Analysis

Total life cycle cost is approximately the same for the five nonthermal systems as shown in Fig. 4. The lowest cost system (desorption) is within 8% of the highest cost system (CWO), with the major differences being in the higher operations and maintenance (O&M) and capital costs associated with the CWO system. The largest contribution to the total cost of all the systems is O&M, followed by disposal and then capital cost.

Fig. 2

Fig. 3

Fig. 4

A typical breakdown of subsystem costs for the acid digestion and desorption systems is shown in Fig. 5. Most subsystem costs are similar for all the systems, with disposal and front end costs comprising the bulk of the system costs followed by stabilization. Front end handling consists of sorting, size reduction, and all the costs associated with receipt and preparation of waste for treatment.

Fig. 5

SUMMARY AND CONCLUSIONS

Five nonthermal treatment systems have been evaluated in the INTS study. These systems are similar in effluent discharge (gas, liquid, and solid). Changes in the waste volume range between a 2% increase and a 20% decrease. Total life cycle costs for each system are also similar. The largest contribution to the total cost of all the systems is O&M, followed by disposal and then capital cost. The major subsystem cost contributors are disposal and front end handling.

FERMCO
Fernald Environmental Management Project
P. O. Box 538704
Cincinnati, Ohio 45253-8704
ABSTRACT
At the end of calendar year 1992, the Fernald Environmental Management Project (FEMP) had approximately 12,500 drums of mixed low-level waste in storage and the Fernald Environmental Restoration Management Corporation (FERMCO) had just begun to develop an aggressive project based program to treat and dispose of this mixed waste. By 1996 the FERMCO mixed waste management program had reduced the aforementioned 12,500 drums of waste once in inventory to approximately 5800 drums. Projects are currently in progress to completely eliminate the FEMP inventory of mixed waste. As a result of these initiatives and aggressive project management, the FEMP has become a model for mixed waste handling, treatment and disposal for DOE facilities.
Mixed waste management has traditionally been viewed as a singular and complex environmental problem. FERMCO has adopted the viewpoint that treatment and disposal of mixed waste is an engineering project, to be executed in a disciplined fashion with timely and economic results. This approach allows the larger mixed waste management problem to be divided into manageable fractions and managed by project. Each project is managed by problem solving experts, project managers, in lieu of environmental experts. In the project approach, environmental regulations become project requirements for individual resolution, as opposed to what had formerly been viewed as technically unachievable environmental standards. With compliant disposition of mixed waste being the primary goal, and achieving compliant disposition as quickly and economically as possible being attendant goals, several general principles have been established in the FERMCO mixed waste program.

1. Wastes must be treated using technology which is proven, reliable, and currently available. Technology development is not performed within the program. Newly developed technology may be considered when that technology will be readily available and proven within a period compatible with the project schedule.
2. Commercial vendors are utilized to the maximum degree possible. The economic incentives for commercial vendors to develop and market treatment technology are utilized and cultivated to the maximum extent prudent.
3. Treatment and disposal technologies which achieve results above and beyond what is compliant are generally undesirable.

Experience at the Fernald site has demonstrated that successful mixed waste management can be achieved through aggressive management of mixed waste management tasks as projects. Projects must be managed around established scope, schedule and budgets. All actions necessary to ensure that the project is successful must be taken. No excuses are acceptable and the project schedule is managed strictly. All projects have a beginning. All projects have an end. Whatever is not on the line between these two events is secondary.

FERMCO SUCCESS AND LEADERSHIP

At the end of calendar year 1992, the Fernald Environmental Management Project (FEMP) had approximately 12,500 drums of mixed low-level waste in storage and the Fernald Environmental Restoration Management Corporation (FERMCO) had just begun to develop an aggressive project based program to

treat and dispose of this mixed waste. FERMCO had also just assigned a manager with strong project management skills to manage and develop a staff to address the FEMP mixed waste inventory.

By 1996 the FERMCO mixed waste management program had reduced the aforementioned 12,500 drums of waste once in inventory to approximately 5800 drums. Projects are currently in progress to completely eliminate the FEMP inventory of mixed waste. As a result of these initiatives and aggressive project management, the FEMP has become a model for mixed waste handling, treatment and disposal for DOE facilities. The balance of this paper addresses fundamental elements of FERMCO's success over the past three years.

DESCRIPTION OF MIXED WASTE PROGRAM

The DOE complex has traditionally viewed mixed waste management as a singular and complex environmental problem. Therefore, personnel possessing expertise in environmental issues alone were assigned to resolve enormous perceived environmental dilemmas.

FERMCO has adopted the viewpoint that treatment and disposal of mixed wastes are engineering projects, to be executed in a disciplined fashion with timely and economic results. This approach allows the larger mixed waste management problem to be divided into manageable fractions and managed by project. Each of these projects is then managed by problem solving experts, project managers, in lieu of environmental experts. In the project approach, environmental regulations become project requirements for individual resolution, as opposed to what had formerly been viewed as technically unachievable environmental standards. The project approach allows waste treatment and disposal to be accomplished while meeting environmental requirements.

The FERMCO mixed waste program was initially established, and continues to be a project based program. Each project has a documented scope, schedule and budget, and a dedicated project engineer. The project engineer is responsible and accountable for all aspects of a specific project, including those activities performed by support organizations.

General Program Principles

Compliant treatment and disposal of waste is an obvious absolute requirement for any mixed waste program. Cost and schedule together form a secondary critical project parameter. Cost and schedule are typically opposing project elements and must be balanced based upon relevant internal and external factors, and good management practice. Scope must be controlled within the confines of good management practice and potentially dynamic technical and regulatory requirements. With compliant disposition of waste being the most important goal in any mixed waste project, and achieving compliant disposition as quickly and economically as possible being attendant goals, several general principles have been established in the FERMCO mixed waste program.

1. Wastes must be treated using technology which is proven, reliable, and currently available. Technology development shall not be performed within the program. Newly developed technology may be considered when that technology will be readily available and proven within a period compatible with the project schedule.

Time is of the essence in any mixed waste treatment and disposal project. Waste must be treated and disposed before the ever changing regulatory environment requires treatment and disposal in a more time consuming, more expensive, and potentially unavailable manner. Waste treatment methods that are proven, reliable, and currently available often are the

same technologies which are economical, commercially prolific, and inherently low risk. Furthermore, DOE complex wide experience has demonstrated that prompt and decisive action is required to solve mixed waste treatment and disposal issues. New and complex treatment methods are not needed for a majority of mixed wastes. Managers of mixed waste programs must utilize the technologies they have available to them today and end their wait for the cure-all technology which is supposedly just around the corner. Mixed waste will never be more easily or economically treated than it can be today.

2. Commercial vendors shall be utilized to the maximum degree possible.

The economic incentives for commercial vendors to develop and market treatment technology must be utilized and cultivated to the maximum extent prudent.

Treatment of mixed wastes utilizing applicable hazardous waste treatment technologies occurs regularly in the commercial sector. Commercial vendors are becoming increasingly aware of the mixed waste challenges and opportunities to be found in the government facilities business area. An environment of such opportunity causes commercial vendors engaged in similar work in other business sectors to make their technology and expertise available within the DOE complex. Furthermore, commercial enterprises can be made aware of government sector mixed waste management issues and these commercial enterprises will perform the research and development to solve these issues at their own expense. Commercial sector vendors are assured to be able to perform any research and development more quickly and economically than the government sector. Mixed waste managers must allow commercial enterprise to work to our advantage and never reinvent the wheel.

3. Treatment and disposal technologies which achieve results above and beyond what is compliant are generally undesirable.

In order to be successful, mixed waste managers must focus on compliant treatment and disposal, not technically ideal treatment and disposal. Mixed waste treatment technologies should be evaluated for compliance with RCRA requirements, including Land Disposal Restrictions, with cost and schedule being considered concurrently. Utilizing technology which achieves results above and beyond that which is compliant is generally more costly than those technologies which are simply compliant. Furthermore, technologies that achieve results above and beyond simple compliance are likely to have a longer planning and operational duration. Expanding costs and extending schedules in implementing waste treatment and disposal activities which exceed regulatory requirements are not good business practices and do not represent proper stewardship of public funds.

At the genesis of the FEMP mixed waste program, the total FEMP inventory of mixed waste was divided into groups which could be treated and disposed, or directly disposed, together. These groupings were generally based upon like treatment standards and similar physical matrices. Each individual waste grouping was then defined as a project.

A scope statement is written for each project. This scope statement must define the project as necessary to completely define the established waste grouping, determine what treatment and disposal alternative will be utilized, implement treatment and disposal, and complete all project closure tasks. The scope statement will define these elements of the project in general terms as technical information available at that time in the project permits. Upon completion of the project scope statement, a

detailed project schedule is prepared. This project schedule includes all tasks necessary to complete the project as defined in the project scope statement. The project schedule divides the entire project into tasks of sufficiently short duration that monthly schedule updates will demonstrate if the project is behind or ahead of schedule.

Each activity contained in the project schedule is resource loaded. The resources for each task include all project management personnel, support organizations, subcontractors and materials necessary to complete that task. The sum of the costs of all resources for all tasks constitute the project budget, excluding contingencies and management reserve. This budget includes all costs which can be attributed to the project from inception through final close-out. Each project is completely cost self-contained.

Disposal under Case-by-Case Variance to LDR - Debris Rule

On May 14, 1993, the U. S. EPA promulgated the second and final Case-by-Case Variance to the Land Disposal Restrictions (58 FR 28506). This variance applied to hazardous waste which met the definition of debris as published by U. S. EPA on August 18, 1992 (57 FR 37194). U. S. EPA defined debris as any man-made material or nonindigenous rock or soil which is at least 60 mm in one dimension. U. S. EPA recognized that many waste streams which contain debris also contain other materials which do not individually meet the definition of debris. For these waste streams, U. S. EPA stated that any waste stream which contains a mixture of debris and non-debris is to be managed as debris if the waste stream is primarily debris based upon visual inspection. Within specified limits, hazardous waste which met this definition of debris could be disposed directly to the land without treatment. U. S. EPA required that all individuals who wished to dispose hazardous debris waste under this variance provide to U. S. EPA no later than August 12, 1993, proof that the individual had made a good faith effort to identify treatment capacity for the hazardous debris waste in question. U. S. EPA stated that contact with ten potential treatment vendors would constitute a good faith effort. The May 14, 1993 variance expired on May 8, 1994.

FERMCO published a Commerce Business Daily (CBD) announcement on June 18, 1993 seeking qualified vendors which could supply capacity to treat mixed debris waste in storage at the FEMP. 50 potential vendors responded to the CBD announcement. No qualified vendors were identified. FERMCO utilized the data collected from the various responses to the CBD announcement to document a good faith effort to identify a qualified treatment vendor in a document pursuant to the U. S. EPA rule making of May 14, 1993 (58 FR 28506). This document was approved by the Department of Energy - Fernald Area Office and transmitted to the U. S. EPA on August 9, 1993. An informational copy of the document was also transmitted to the Ohio EPA.

FERMCO identified 368 containers of mixed debris waste which would qualify for land disposal under the aforementioned rule making. All 368 containers were inspected for free liquids using real-time radiography. Containers which held free-liquids were emptied onto a sorting table. All mixed debris waste was placed back into the container from which it was removed and liquid waste removed from the container was placed into storage for disposition as part of the Liquid Mixed Waste Project discussed later in this document.

The mixed debris waste identified for land disposal was divided into two groups for the purpose of sampling, analysis and profiling pursuant to

Envirocare of Utah's waste acceptance criteria. These groupings were established based upon the physical nature of the debris waste, the manner in which the debris waste was generated and the potential contaminates of concern present in the waste.

Samples were extracted from a statistically determined number of randomly selected waste containers in each waste grouping by FERMCO hazardous materials workers. These samples were analyzed by a State of Utah certified analytical laboratory. Envirocare waste profiles were completed by FERMCO Hazardous and Mixed Waste Management personnel for each waste grouping based upon the Utah certified data and transmitted to Envirocare for review and approval. Upon approval of these profiles, Envirocare provided FERMCO with a Notice to Transport (EC-1800). This notice documents Envirocare's approval to ship the waste described on the submitted profile. FERMCO released the first shipment of six total shipments of mixed debris waste to Envirocare on April 12, 1994 and released the sixth shipment on April 21, 1994.

All mixed waste at the FEMP which met the definition of debris and was eligible for disposal at Envirocare was disposed during the aforementioned waste disposal campaign.

Disposal of D018-D043 & F-Listed Waste

On September 19, 1994 (59 FR 48045), U. S. EPA promulgated a final rule establishing the treatment standards for newly identified toxicity characteristic waste. The types of waste referred to are those hazardous wastes carrying waste codes between D018 and D043 inclusive. This rulemaking went on to state that for hazardous wastes carrying these waste codes which also contain radioactive materials, the effective date of the rule is September 19, 1996. Because this final rule does not apply to mixed waste until September 19, 1996, mixed wastes carrying waste codes between D018 through D043 inclusive may be disposed to the land without treatment until that date.

In response to this rulemaking, FERMCO identified all mixed waste carrying only waste codes between D018 and D043 inclusive. As a part of the same campaign, FERMCO identified a population of listed mixed wastes carrying 'F' codes which exhibited concentrations of the RCRA treatment constituent of concern below the established RCRA Land Disposal Restrictions treatment standard. Listed wastes which meet treatment concentration standards without treatment may be disposed as if that waste had been in fact treated. The specific waste streams identified were a D018 through D043 trash waste stream and a cement stabilized F-listed waste stream.

Each container of D018 through D043 mixed waste was examined utilizing real-time radiography. Any container found to contain free liquids was excluded from shipment to Envirocare and re-assigned to the proper mixed waste treatment project.

Samples were extracted from a statistically determined number of randomly selected waste containers in the D018-D043 and F-listed waste streams by FERMCO hazardous materials workers. These samples were analyzed by a State of Utah certified analytical laboratory. Envirocare's waste profiles were completed by FERMCO personnel for each of the two subject waste streams based upon the Utah certified data and transmitted to Envirocare for review and approval. Upon approval of these profiles, Envirocare provided FERMCO with a Notice to Transport (EC-1800). This notice documented Envirocare's approval to ship the waste described on the submitted profile. FERMCO released the first of four total shipments

of cement stabilized F-listed mixed waste to Envirocare on March 3, 1995 and released the fourth shipment on March 6, 1995. FERMCO released the only shipment of D018-D043 mixed waste on March 30, 1995.

Liquid Mixed Waste Project

The Liquid Mixed Waste Project encompasses approximately 2,300 containers of mixed liquid waste ranging in size from 5 gallons to 110 gallons. Like the Mixed Waste Stabilization Project and the Mixed Waste Chemical Treatment Project described later in this document, this project is being documented under CERCLA Removal Action 9, "Removal of Waste Inventories." The CERCLA Work Plan for this project was approved by the U. S. EPA and the Ohio EPA prior to the initiation of waste transfer operations. Many of these 2,300 containers hold both liquids and sludges. The liquids will be treated at the K-1435 TSCA Incinerator at the Department of Energy's Oak Ridge facility and will likely be disposed by TSCA Operations. The sludges in these drums will be treated and disposed as part of the Chemical Treatment Project described later in this document.

The TSCA Incinerator accepts liquid wastes in bulk tanker truck deliveries only. For this reason,the subject liquid wastes must be bulked before shipment. Furthermore, the 2,300 containers of waste included in this project represent in excess of 100 separate waste streams generated at different times and by various means, demonstrating that each of these waste streams is within the waste acceptance criteria at the TSCA Incinerator would be cost and schedule prohibitive.

For the purpose of bulking, the various waste streams were divided into compatibility groups based upon information available from the characterization file for each of the various waste streams. Five compatibility groups were identified which encompassed all of the waste streams within the 2,300 container population. In order to assure compatibility of the wastes when actual commingling of the wastes occurs in the field, samples of the various generic types of waste from each compatibility group were secured. These samples were combined in the FEMP analytical laboratory in the same order and ratios in which the actual wastes in the field would be combined. Laboratory commingling of these waste samples and monitoring the commingled waste for possible physical or thermal reactions was performed as per ASTM Method 5058, Standard Test Method A. No physical or thermal reactions were observed in any of the combined waste forms.

In order to combine the five compatibility groups of waste, portable tanks generically known as "Frac Tanks" were rented. A total of six tanks were rented in order to provide one backup tank in the event of a leak or other unplanned occurrence in any of the five primary tanks. The portable tanks are approximately 40 feet in length, 8 feet in width, 11 feet in height, and have a total capacity of approximately 21,000 gallons. Each tank is equipped with a single tandem axle for transport of the tank while empty only. The tanks are also equipped with side and top manways, OSHA compliant stairs and catwalks leading to the top manway, high-level alarms, bottom loading fittings with lockable ball valves, fluid level indicators, and carbon air emissions filters.

The six tanks were field installed within a poly compound inflatable containment system. This poly containment system is physically similar to and resembles a rubber raft. The secondary containment was fabricated of materials resistant to the various wastes to be placed in the portable tanks.

The design of the temporary waste storage area comprised of the six portable storage tanks and inflatable secondary containment was designed to comply with State of Ohio regulations regarding tank systems for storage of hazardous waste. The primary driver from Ohio RCRA regulations for the temporary waste storage area is the capacity of the secondary containment. The secondary containment must have a volume adequate to contain 10% of the total volume of waste stored in the various tanks within the containment or the volume of the largest tank within the containment, whichever is largest, in addition to a 25 year rain event occurring over a 24 hour period. In this project, the volume of the largest tank is the controlling factor.

The transfer of liquid waste is achieved with the use a 2 inch diameter dual diaphragm pneumatically powered pump. All wetted surfaces of the pump are stainless steel and the diaphragms are Teflon. The pump is connected to the bottom loading valve of the tank to which the liquid waste is to be transferred via a 2 inch diameter high pressure Teflon lined and wire reinforced hose. The suction side of the pump is connected via an identical hose to an approximately 48 inch long, 2 inch diameter stainless steel tube with a 1/16 inch stainless steal screen welded over the end of the tube. Each of these hose sets is equipped at each end with stainless steel ball valves and female stainless steel camlock fittings. The temporary storage tanks and pump are equipped with male stainless steel camlock fittings. The transfer of liquid waste is achieved by configuring the hoses in the aforementioned manner, starting the pump, and carefully placing the end of the stainless steel tube into the waste storage container until all liquids within the container have been transferred. All power tools utilized on this project are pneumatically driven and sparkless, all hand tools are sparkless, and all flashlights used are intrinsically safe.

Transfer of liquid phase waste from existing storage containers into portable tanks began on May 1, 1995 and was completed July 19, 1995. Sampling personnel from the Oak Ridge facility sampled Batch 1 pursuant to TSCA Incinerator Waste Acceptance Criteria on May 26, 1995 and Batch 5 on July 25, 1995. As of September 19, 1995, FERMCO has made twelve total tanker shipments of waste to the TSCA Incinerator. The first shipment was released from the FEMP on July 27, 1995 and the twelfth shipment was released on September 19, 1995. The twelve shipments of waste that have been made comprise a total of 165 cubic meters of liquid mixed waste. A total of 123 cubic meters of liquid waste remain to be shipped. Shipment of these liquid wastes is expected to be complete during the spring of 1996. Waste shipments are currently suspended for the winter due to cold weather and resultant thickening or freezing of the waste.

Mixed Waste Stabilization Project

Approximately 1,550 containers, primarily 55 gallon drums, of solid phase waste contaminated with RCRA regulated heavy metals are stored at the FEMP. This waste are being treated onsite utilizing mobile stabilization equipment and disposed at Nevada Test Site.

This project is being documented under CERCLA Removal Action 9, "Removal of Waste Inventories." Documenting this project as a Removal Action allows RCRA regulated wastes to be treated at the FEMP without a RCRA Part B permit for treatment. CERCLA and its implementing regulations, "The National Oil and Hazardous Substances Pollution Contingency Plan," state that actions under CERCLA are not subject to state administrative requirement, i.e. a RCRA Part B permit, in states with an authorized RCRA

program, such as Ohio. However, actions under CERCLA are subject to state substantive requirements.

On December 19, 1994 a Commerce Business Daily announcement was published describing the waste to be stabilized, stating that a Request for Proposal for onsite stabilization of the waste described would be available in the future, and requesting that interested and qualified vendors provide a statement of interest to FERMCO. Approximately 70 statements of interest were received.

On April 10, 1995 a Request for Proposal (RFP) for mobile mixed waste stabilization services was transmitted to all respondents to the Commerce Business Daily Announcement. This RFP included descriptions of all waste to be stabilized, including a description of the general physical character of the waste and applicable RCRA waste codes for each waste stream. The RFP also included other documents necessary for a vendor to prepare a proposal, such as the Mixed Waste Stabilization Project approved Project Plan. Proposals were accepted on May 2, 1995 and the stabilization subcontract was awarded on May 30, 1995.

The Ohio EPA stated that their review and approval of detailed equipment drawings and process procedures for this project were necessary before treatment may begin. Many types of stabilization equipment are utilized for the stabilization of hazardous waste. Therefore, the details requested by Ohio EPA can not be provided until a vendor is chosen and the requested information can be submitted to FERMCO by the vendor. After award of the stabilization subcontract to the successful vendor, the vendor has approximately 30 days to submit documentation listed in the RFP to FERMCO, including detailed equipment drawings and operational procedures. This detailed information will be combined with various types of environmental information required in a CERCLA work plan and submitted to the U. S. EPA and Ohio EPA for review and approval. Once approval of the work plan is secured from both agencies, FERMCO will authorize the vendor to mobilize and begin stabilization activities. Stabilized waste will be placed in half height white metal boxes and shipped to the DOE Nevada Test Site for disposal.

The CERCLA Work Plan for the stabilization project, including the engineering mentioned above, was provided to the Ohio Environmental Protection Agency (Ohio EPA) and the U. S. Environmental Protection Agency on September 7, 1995. The FEMP received approval to proceed with stabilization field operations from the Ohio EPA on September 29, 1995. FERMCO authorized the stabilization subcontractor to proceed with mobilization of treatment equipment immediately. FERMCO completed an Operational Readiness Assessment of the Stabilization Project on November 20, 1995 and received DOE-Ohio Field Office permission to proceed with operations on November 21, 1995. The stabilization subcontractor began stabilizing waste on November 16, 1995 and as of February 9, 1996 had stabilized a total of approximately 1100 drums of waste.

Mixed Waste Chemical Treatment Project

This project encompasses approximately 4,000 containers of mixed waste which represent all the mixed waste which will remain in the FEMP mixed waste inventory after completion of the previously discussed projects. The wastes included in this project represent the most challenging wastes to treat at the FEMP. A majority of the wastes in this project will require multiple treatment steps or technologies to achieve compliance with RCRA Land Disposal Restrictions. This project is termed the Chemical

Treatment Project because the multiple treatment steps required to treat these wastes will be chemical in nature.

A Commerce Business Daily announcement was published on March 16, 1995 requesting expressions of interest from qualified parties to provide chemical and physical treatment for various types of mixed waste. As of May 30, 1995, 36 responses to the announcement had been received. Responses have been received from well established and proven vendors as well as previously unknown vendors of unknown capability. The expressions of interest received have varied in form from detailed explanations of the vendor's experience and capabilities to simple requests to receive any future Request for Proposal.

Current schedule projections indicate that the Request for Proposal for mobile Chemical Treatment will be issued near the end of February 1996. Completion of the Chemical Treatment Project is scheduled for November 1997.

Treatment flow diagrams for the various waste streams in this project have been developed. Treatment processes with multiple treatment steps for one waste stream are referred to as "treatment trains." Various combinations of the following technologies are anticipated to be necessary:

1. Solvent Extraction - Sludges and Soils
2. Decontamination - Lead Solids
3. Macroencapsulation - Lead Solids
4. Deactivation - Reactives and Oxidizers
5. Neutralization - Acids and Caustics
6. Precipitation - Barium Salts and Mercury Salts
7. Washing - Debris
8. Amalgamation - Elemental Mercury
9. Chemical Oxidation - Waste Waters

CONCLUSIONS

Remove Historic Barriers to Success: Mixed waste can be managed compliantly, effectively and economically in a timely manner. Do not allow the traditional reasons why mixed waste can not be treated and disposed prevent project progress. Barriers to successful management of mixed waste are usually issues of perception, not fact. Aggressively remove barriers to success.

Utilize Technology Which Exists: Utilize mixed waste treatment technology which is proven, reliable and currently available. Technology exists to treat and dispose most mixed waste streams. Avoid spending time and money on developing new technologies or further researching existing technologies. Do not accept the "not invented here" argument. Implement mixed waste treatment projects utilizing current technology now. If an option exists; use it. Mixed waste treatment is cheaper now than it will ever be again.

Take Advantage of Commercial Sector Resources: Utilize subcontractors to treat waste whenever possible. The private sector recognizes their potential for profit if they can solve the DOE complex's mixed waste challenges. Allow subcontractors to absorb the cost of research, development, equipment procurement, and process risk. Take advantage of commercially proven expertise in waste treatment. Do not perform work in house that someone else can do for you cheaper, faster and better.

Be Compliant, Not Perfect: Plan treatment and disposal projects which achieve compliance, not the perfect solution. The ideal or most advanced

technology to treat waste is not necessary. Use the quickest, most economical, safe and compliant treatment and disposal option available. Projectize the Work: Divide your total inventory of waste into manageable portions that have a beginning and an end. Determine the scope, schedule and budget for the work. Assign responsibility, authority, accountability, and resources. Everything has a beginning. Everything has an end. What is not on the line is irrelevant. Get on the line. Start now. Finish!
Take Action: If waste can be disposed without treatment; dispose it. Determine what compliant treatment is available for waste requiring treatment and aggressively move forward to accomplish that treatment. Take advantage of regulatory latitude. Do not wait for new technology. Tomorrow never comes. Move forward today. Their is no excuse for failure to act on available treatment and disposal options. Start! Finish!

ABSTRACT

Accurate characterization and control of plasma torch facilities for mixed waste remediation is currently a major effort at the Diagnostic Instrumentation and Analysis Laboratory at Mississippi State University. This work is being supported by the U.S. Department of Energy within the Office of Science and Technology (EM-50) of the Office of Environmental Management. Although plasma torch systems have been used commercially for many years, most notably in material science applications and for the treatment of incinerator ashes, the extension to mixed waste presents challenges. Specific issues are concerned with the composition of the input waste stream, the longevity of torch components such as electrodes and vortex generators, refractory wear, the quality of the final waste form, downstream gas compositions and the performance of air pollution control devices. Evaluation of these factors requires a systematic approach including instrument development, materials studies, systems integration, modelling and control system development.

Over the past two years, work at DIAL has proceeded in these areas. The plasma torch facility has been assembled. Testing of refractories capable of withstanding the harsh environments in the torch furnace have been reported. Work on instrumentation for characterization of the plasma and

for the assessment of gas stream conditions, chemistries, and emissions has been performed. Efforts directed at non-intrusively measuring glass viscosities are in progress. Knowledge of facility parameters and specific measuring objectives (heavy metals, inorganics and organic concentrations, viscosities, and plasma properties etc.) provide usable data which can be related to the operation of the plasma torch and associated facility components. Integration of these data into a suitable control scheme allows a precise means for efficient operation of the system. In what follows the DIAL plasma torch facility, some of the instrumentation being applied to the characterization of the process, and the control systems are described.

PLASMA TORCH FACILITY

DIAL's thermal test facility includes two plasma torch systems as well as a combustion test stand. Both plasma torches are hollow electrode DC torches. The smaller of the two systems uses a 100 kW plasma torch mounted in a four foot diameter chamber capable of vacuum operation. The chamber is fitted with several optical ports and is used strictly for "clean" experiments such as plasma diagnostics and instrument development. The 100 kW torch can be used in either the transferred or the non-transferred mode of operation. In non-transferred mode the plasma torch produces an electrical arc from its internal hollow anode electrode to an electrode which is on the front of the plasma torch. A flow of gas through the torch produces a plasma plume which exits at the front of the plasma torch. In transferred mode the electrical arc from the internal hollow electrode attaches to an external electrode. A graphite billet is used for the external negative electrode for the 100 kW system.

The larger system is a 250 kW hollow electrode DC torch, see Fig. 1. This system is intended for actual vitrification experiments. The plasma torch has electrical 3-axis position control (as does the 100 kW system) which is useful for power control and for maintaining a consistent temperature throughout the melt. This plasma torch is usually operated in the transferred arc mode. A graphite electrode at the bottom of the vessel acts as the negative electrode until a sufficient amount of soil or surrogate waste is added to the system and a conductive melt is established. The melt then acts as the negative electrode. Four Optics ports on the top of the vitrification vessel allow optical access for diagnostic instrumentation. Optical penetrations are also located directly downstream of the furnace.

Fig. 1

The 250 kW system is used for instrument and control system development as well as for vitrification research and testing. Soil from the Savannah River site as well as a surrogate material designed by WSRC have been vitrified using this system (1,2). A series of DIAL/WSRC refractory tests were performed using 32 refractory samples to determine what type of refractory might be useful in plasma torch vitrifiers.

The offgas from both of these plasma torch systems is fed to a combustion test stand which can be used to provide secondary combustion or simply as a pathway for the plasma systems offgas to get to the pollution control system. Optical access is provided at many locations along the test stand channel. The pollution control system includes a quench, venturi scrubber, and packed column tower. This system provides both particulate removal and acid gas neutralization. Dual HEPA filters follow the wet system and are used to remove smaller particulates. Figure 1 shows a block diagram of the 250 kW system and the pollution control system.

DIAGNOSTIC INSTRUMENTATION

Many parameters are of interest for characterizing and controlling a plasma torch facility. Specific diagnostics can be applied to measurements of the input waste stream, plasma properties within the torch furnace, metal, particulate, and gaseous emissions, and specialized techniques for evaluating the quality of the final waste form. Methods for evaluation of the partitioning of nuclear species are underway at various laboratories and are not discussed here. A brief description of some of the instruments under development are given below. Work on sensors for inlet waste streams is planned. Some of the diagnostics, for example, FTIR and LIBS, may be suitable as continuous emission monitors as well as for process control. Additional work is in progress for fully characterizing the benefits of these applications.

Plasma Diagnostics

A major concern with the use of plasma torches for hazardous waste vitrification is the need to prolong electrode lifetime (3,4,5). Because unchecked erosion of the electrode into the torch cooling system may lead to catastrophic failure, effective monitors for electrode erosion and wear are needed. The goals of the present work include characterizing several fundamental torch plasma parameters, using these results to develop monitors for torch electrode wear and failure, and investigating techniques for extending the electrode lifetime. Studies have been performed to evaluate the stability of a plasma torch arc and its suitability for spectroscopic interrogation. Subsequent investigations have been concerned with obtaining temperature and electron density profiles of the torch arc, and with evaluating the torch electrode erosion rate through the observation of atomic copper emissions from the plasma. Initial studies have also been performed using electrodes doped at a given depth with an indicator material. Monitoring the plasma emission for signals associated with this indicator has been used to signal erosion to a particular depth.

Experimental studies are currently carried out using the 100 kW plasma torch operated in the transferred mode using nitrogen, air, or argon. A single 2f lens is used to form a 1:1 image of the torch arc on a fiber optic cable. This cable is routed to a 0.5 meter spectrometer and the resulting spectra recorded using a charge coupled detector (CCD). The input to the fiber is mounted on a horizontal translation stage, allowing the observation of spectral emissions from any position across the arc image. This horizontal scanning capability allows the reconstruction of profiles of the plasma temperature, electron density, and emission intensity. These results may be compared with two-dimensional images of the plasma arc obtained using narrow band interference filters and a CCD camera. Emission from a specific element (e.g. copper generated by electrode erosion) may be imaged by selecting appropriate interference filters. Although the gas flow from the torch rapidly becomes turbulent after exiting the plasma torch electrode, spectral emissions from near the electrode orifice are quite stable and are amenable to spectroscopic interrogation.

Using the relative intensities of atomic emissions from the plasma allows a Boltzmann plot determination of the plasma temperature. For example, during nitrogen operation, line-of-sight average temperatures ranging from approximately 6000 K at the arc edge to approximately 12,000 K at the arc center are consistently observed. The electron density profile of the plasma torch arc may be determined from the full Stark width of the

hydrogen b line emission (6). The addition of a small amount of hydrogen into the torch operating gas allows the observation of this line. For nitrogen operation the electron density profile rises smoothly from a minimum of approximately 6 x 1020 e-/m3 at the arc edge to 2 x 1022 e-/m3 at the arc center. As part of an effort to monitor the erosion of the primarily copper torch electrode, copper atomic emissions are evaluated as a function of position within the plasma arc. These results clearly demonstrate that the most intense copper emission occurs at the edge of the plasma arc.

One of the most promising results obtained thus far has been the use of a doped electrode to signal erosion to a particular depth. Electrodes are modified by drilling a small hole (or several holes) parallel to the electrode axis, then filling this hole with silver solder. Atomic silver emission is detected from the plasma only after the surface of the electrode is eroded to the depth of the silver solder. In Fig. 2, emission spectra recorded before and after erosion into the silver solder are depicted. Silver emission is clearly visible at 520.8 nm after arc contact with the solder, yet clearly absent before. This results suggests that doped electrodes provide a simple yet effective monitor for electrode wear, and may be used to warn of an imminent failure of a torch electrode.

Fig. 2

Methods For Determining Viscosity

A critical parameter in the vitrification process is the viscosity of the molten glass which has an effect on the quality of the waste form and the processing of waste (7,8). Two methods are currently being investigated as on-line monitors. The first is directly applicable to the measure of viscosity in a rotating furnace which is an integral component of many plasma torch facilities. The method is based on correlation of the fluid flow dynamics with the viscosity at different rotational velocities of the furnace. The second method being developed will measure the viscosity of the molten glass as it is being poured. The technique involves determining the reflection coefficient of ultrasonic shear waves from a solid-molten glass interface. This coefficient is a function of the viscosity of the molten glass. Methods are being investigated using laser generated shear waves, as well as with conventional ultrasound.

Work done at Westinghouse Savannah River Company (WSRC) has established a glass viscosity window of 20-100 poise for the Defense Waste Processing Facility (DWPF), and also for other melters to be used for low-level wastes (9). If the viscosity is too low, < 20 poise, excessive foaming may occur. Also, increased convection currents in the glass will cause increased refractory and melter electrode erosion and/or corrosion. Higher viscosity glasses (> 100 poise) may lead to plugging of the tap and/or voids in the product. Additives (fluxes containing alkali metals) can be used to reduce the viscosity of molten glass, but these additives also weaken the molecular structure of the glass. Thus, excessive or unnecessary use of viscosity reducing fluxes will be detrimental to the ability of the glass to pass leachability tests.

Viscosity Measurement in Plasma arc Centrifugal Treatment (PACT) System

The PACT system consists of a large, cylindrical furnace vessel, open at the top, which rotates about its vertical axis (10,11). Typically, this cylindrical drum might be 6 feet in diameter and will rotate at about 40-50 rpm. The wastes to be vitrified are introduced into the top of the drum. The rotation of the drum and its contents (untreated waste and the

glass products of vitrification) creates centrifugal forces which force the drum contents toward the outer periphery of the drum. A tap is located in the center of the furnace floor; however, centrifugal forces keep the drum contents away from the drain hole. As the drum contents rotate, they periodically pass underneath a plasma torch. After sufficient wastes have been fed into the drum, the feeding is stopped, and the wastes are processed until they are vitrified. The rotation of the drum is slowed, and the glass flows through the tap and into a mold.

DIAL has developed a novel idea for measuring the viscosity of the glass in the PACT system prior to a pour. This idea takes advantage of the fact that, in the PACT system, the glass whose viscosity is to be measured is contained within a rotating drum. The behavior of rotating liquids has been the object of intense study. Greenspan (12) discusses the "spin-up" problem, in which a liquid-filled container at rest is suddenly started rotating at a constant angular velocity. The liquid in the container is also initially at rest, and gradually acquires the same rotation speed as the container. The characteristic spin-up time is proportional to

Eq. 1

where W is the angular velocity of the container, L is a characteristic length scale of the container, and n is the liquid viscosity. The time required for the liquid in a rotating container to adjust to a change in the rotational speed of the container is hence dependent on the viscosity of the liquid. The concept involves therefore changing the rotational speed of the furnace and monitoring the response of the glass. A numerical model has been developed for the dynamics of the spin-up process, and an experimental investigation is underway.

Laser Ultrasonic Viscosity Measurement

Theoretical results show that the shear wave reflection coefficient from a solid-fluid interface is a function of the viscosity and density of the fluid (13,14). The reflection coefficient is a complex number and either its phase or magnitude can be used to calculate the viscosity. The density and shear wave speed of the solid also enter in as factors. By choosing solids with desirable properties, the reflection coefficient can be made sensitive to different viscosity ranges. With this in mind, the goal is to determine the actual viscosity in the 20-100 poise range to within 10 poise and to be able to determine when it is not within this range. Further discussions on ultrasonic methods are given elsewhere (14,15).

In conjunction with the theoretical analysis, a series of experiments has been performed using conventional ultrasonics. In order to measure the reflection coefficient of shear waves, an ultrasonic shear wave transducer was mounted on one end of a solid block. The other end of the block was immersed in the viscous liquid. For most of the experiments a 2.25 MHz shear wave transducer was used in pulse-echo mode. A standard ultrasonic pulser unit served to excite the transducer and receive and amplify the reflected signals, which were recorded with a digital oscilloscope and transferred to a computer. Using algorithms developed during the theoretical studies, these signals were processed to predict the viscosities of the various liquids tested. Results are collected in Table I. Agreement within 10 poise was obtained in many of the trials.

Table I

Experiments were also performed to demonstrate the feasibility of laser ultrasonics to measure viscosity. The technique is basically the same as with conventional ultrasonics except that ultrasound is generated by a

pulsed laser and detected using a laser interferometer. The technique is completely noncontact as far as the transducer is concerned. The feasibility of this technique was demonstrated using piezoelectric transducers instead of an interferometer to detect the reflected shear wave. The results of these experiments are shown in Table II and indicate good agreement.

Table II

Further development in both the conventional ultrasonic and laser ultrasonic approaches is in progress. These efforts include further development of an interferometer detector, studies on improving the signal to noise ratio of the measurements, and pilot scale experiments.

Metals Emissions And Glass Composition

Determination of metals partitioning within the plasma torch facility is of interest from process control and regulatory perspectives. DIAL is currently investigating three methods, Laser Induced Breakdown Spectroscopy (LIBS), Laser Optogalvanic Spectroscopy (LOGS), and inductively coupled plasma (ICP) spectroscopy where the ICP is operated on air. LIBS can serve a dual role for compositional determination of the glass and for process control. The ICP is being designed as a portable field unit and may also find application as a downstream module for low-flow gas streams as an organic destruction unit. LOGS has the potential for quantification well below current regulatory levels and will most likely find use as an emission monitor. Details of the ICP work can be found in a companion paper submitted to this conference.

Laser Induced Breakdown Spectroscopy (LIBS)

LIBS is a laser based advanced diagnostic technique for measuring the concentration of various elements in the test medium (16-21). In the LIBS technique, a pulsed laser beam is focused at the test point to produce a spark. The spark in the focal region generates a high density plasma which produces and excites various atomic elements in the test volume. Atomic emission from the plasma is collected with a collimating lens and sent to the detection system. The intensity of the atomic emission lines observed in the LIBS spectrum are then used to infer the concentration of the atomic species.

DIAL has been actively involved in evaluating various application of LIBS for environmental remediation (16-22). LIBS has been applied to a harsh, turbulent and highly luminescent coal fired magnetohydrodynamic (MHD) gas stream (17). A preliminary study of the determination of Uranium (U), Plutonium(Pu) and Neptunium(Np) by LIBS has also been performed (23). The details of the LIBS experimental setup is described in references 16 and 22. In brief, a frequency doubled 532 nm Nd:YAG laser beam is focussed at the sample. The emission light from the laser-induced plasma is sent to the detection system by an optical fiber. Data acquisition and analysis were performed using a notebook computer. A portable, mobile, and versatile LIBS system has been developed for various applications. It has been used to measure the concentration of toxic metals in the off-gas from a Savannah River (SR) surrogate vitrified with DIAL's plasma torch facility (18). Off-gas measurements have also been made at the Western Energy Technology Office (WETO) torch facility/Mountain State Energy (MSE), Montana (19). In addition, the performance of this system has been evaluated in the Advanced Analytical Instrumentation Demonstration (AAID) test at Science Applications International Corporation (SAIC)'s STAR Center, Idaho Falls, ID. (20) Various LIBS measurements have been evaluated to develop a process control for hazardous waste remediation

(22). It has been used to monitor the major species in the melt glass from an EnVitco melter test run at Clemson University (23). The results of the LIBS measurements of the concentration of metal in the off-emission and melt glass have showed that LIBS can provide the information about metal partitioning during hazardous waste thermal processing. Recently, LIBS spectra were recorded in the off-gas of DIAL's plasma torch facility during various SR surrogate test runs. LIBS spectra in a wavelength region of 404-421 nm was used to measure the concentration of Pb, Ce and Fe. Broad vibrational peaks due to CN are also observed in this region. CN is produced from the reaction of C and N which are produced in the spark. Other elements present in the off-gas emission were identified from spectra in various spectral regions. Those identified were: Al, B, C, Ca, Ce, Cd, Cr, Cs, Fe, K, Mg, Mn, Na, Pb, Si, Ti, Y, and Zr. Special attention was given to the spectral regions with Pb, Cr, Cd, Cs, and Ce atomic transitions. The LIBS spectra were also collected continuously to study the variation of metal concentration with time. The typical sample rate in this test is 3.5 seconds. Generally, the metal concentration increases right after new feed was added to the plasma torch. Then the metal concentration was nearly constant for a few minutes and then starts decreasing. However, this also depends on the arc attachment point in the melt glass which is quite random. The concentration ratios of various metals are also monitored with time. Figure 3 shows the concentration of Cr, Fe, Pb, and Ti inferred from the LIBS data collected on March 6, 1995. The time that briquettes were added is marked with an x in the figure.

Fig. 3

Laser Optogalvanic Spectroscopy: (LOGS)

The concentration of metallic species entrained in the off-gases of practical thermal treatment systems can be monitored in real time at ultra-low levels using DIAL's Laser Optogalvanic Spectroscopy (LOGS) system by extracting a sample of the off-gases via a slipstream. Since the metallic species in the downstream portion of the off-gas system exist primarily as particles rather than as elemental or molecular species, an atomization source is used to atomize the particles, permitting the measurements of low concentrations. In a LOGS measurement, a pulsed, tunable laser is tuned into resonance with a transition of a species (atomic or molecular) in the atomization source, temporarily increasing the excited state concentration of that species. Because the energy necessary for ionization is less for an excited electronic state than for the ground state, the rate of ionization temporarily increases due to laser-enhanced electron impact ionization, and/or due to direct laser photoionization. The process can be monitored as a transient (tens of microseconds) voltage change if a high voltage electrode (relative to ground) is inserted into the atomization source. The concentration of the species is obtained by relating the magnitude of the LOGS signal intensity to the concentration of the species of interest via a calibration curve. Only the LOGS response in the vicinity of the electrode is probed. Because LOGS uses electrical rather than optical detection, this technique alleviates problems associated with monitoring small absorptions or weak fluorescence in the presence of a strong optical background signal. LOGS has inherently greater sensitivity than optical detection techniques because the collection of charges can be significantly more efficient than the collection of photons. Table III compares our current limits of detection for LOGS for selected RCRA and

radioactive metals to those attainable by air ICP, (24) which is a competing real-time, on-line technology. It should be emphasized that air ICP values in Table III are the current state of the art and the LOGS values reported in the table were obtained without optimizing the operating conditions; optimization of the LOGS operating conditions (higher detection electrode voltages, higher laser powers, optimization of detection electronics) will decrease these LOGS limits of detection by between one and, in the best cases, three orders of magnitude.

Table III

Permanent Gases and Products of Incomplete Transformation

Current studies aimed at characterizing the gas streams resulting from air and nitrogen plasma operations are contained in a companion abstract submitted to this conference. Fourier Transform Infrared (FTIR) spectroscopy studies are also being directed toward the determination of particle size distributions. Such measurements are important in mixed waste remediation facilities for measurements where conventional extraction techniques are restricted owing to radiation guidelines. Other efforts which will be described in more detail in the accompanying abstract include an advance MS/MS method and the use of GC/MS and gas analyzers.

Fourier Transform Infrared Spectroscopy

Fourier transform infrared (FTIR) spectroscopy offers a number of advantages for process screening and component quantification. The technique is based on the absorption or emission of infrared radiation as a molecule undergoes a transition from one vibration-rotation level to another. Every molecule, except homonuclear diatomics (N2, O2, etc.), will exhibit a unique infrared signature. The extent of absorption or emission of the infrared light will depend on the concentration of the molecules present in the flow, the gas temperature, and the effective optical path length. The method is rapid and capable of quantifying many molecules from a single measurement.

A number of different applications to mixed-waste remediation processes are being pursued at DIAL. These studies include on-line, non-intrusive, emission and absorption measurements, particle scattering studies, and conventional sample extraction. Certain limitations will apply to the on-line and extractive measurements. In a non-intrusive configuration the path length will be limited by the distance across the facility channel, whereas the extraction measurements are performed at a longer distance consequently resulting in lower limits of detection. The on-line measurements do not involve sample handling. In this case, however, instrument calibration may be complicated by the high facility temperatures as compared to those conveniently available for establishing calibration sets in the laboratory. It is anticipated that both on-line and extractive instrument configurations will find application in providing data for control schemes.

Measurements have recently been conducted on the PACT plasma torch facility at WETO operated by MSE (25). Extractive measurements were conducted upstream and downstream of the NOx control unit while passive (emission) spectra were collected at a high temperature facility location between the plasma torch furnace and the secondary combustor. The purpose of the emission experiments was to examine the composition of the gas stream as it exited the torch and to determine a gas stream temperature at the facility location. This FTIR emission experiment offers an advantage over conventional thermocouple measurements in that heat

transfer corrections are not necessary, concerns about corrosion of the probe are eliminated, and higher temperatures are measurable.

Typical emission spectra are collected in Fig. 4. Molecules which account for the band and line intensities are H2O, NO, and CO2. Emission lines from CO were not observed in any of the spectra downstream of the torch furnace indicating that any organics present in the feed were converted to CO2. Determination of a rotational temperature from the NO fundamental lines was hampered by the interference from H2O. A spectrum of H2O at a temperature of 1200 K and a concentration of 3% was generated using the HITRAN data base and the FASCODE infrared signature software (26,27). The synthetic H2O spectra was then subtracted from the emission spectra to leave the NO rotational envelope which was then analyzed based on the fact that the different rotational lines will be populated according to the Boltzmann distribution (28). Corresponding temperatures averaged 1070 K or 1466 F. The subtraction process, described above, did not seem to alter the determined temperature but does tend to increase the scatter in the plots.

Fig. 4

Previous work on high temperature combustion gas streams indicated that the spectra will systematically change with changes in combustion conditions (29). This work resulted in a patent application and the corresponding instrument may find application to secondary combustion of plasma furnace gas streams.

CONTROL SYSTEMS

DIAL's plasma torch and process controls structure depicted in Figure 5 consists of a supervisory control, coupled with an artificial intelligence (AI) advisor, with monitoring links to various diagnostic instruments. This provides both robust operation and flexibility, with embedded graphics, data archival, on-line reconfigurability, and correlation capability as some of the convenient features. The system will accommodate 40 inputs and 20 outputs; more with minor modification. A list of I/O presently configured is given in Table IV.

Fig. 5

Table IV

Diagnostic instrumentation for use in control schemes must meet specific requirements. The systems must be sufficiently sensitive and rugged. Factors such as signal acquisition, control structure, and actuation must all be considered in the development of a viable control package.

Signal acquisition can span considerable range. For some diagnostic monitors, the control system must accommodate a few seconds inherent latency. Other detectors provide information over a spectrum that must be reduced to a few variables. The control system at DIAL has a dual acquisition structure - one for continuously available signals, and another for asynchronous data. This allows inferential techniques to be applied as needed.

The diagnostic instruments are being developed for specific end uses. In some cases the systems are expected to provide valuable information at multiple locations within a facility. Examples of this are the LIBS and FTIR systems. Additional experimental effort is underway for identification of the most appropriate uses of the diagnostics with respect to the control structure. This work involves the consideration of all aspects of the facility, waste preparation, the primary chamber and final waste form, the downstream components, and associated emissions.

Actuation is an item of concern in vitrification processes, since there are only a few variables available for actuation. Generally these must exceed the number of quantities of concern (metal volatization, other off-gas hazards, product quality, volume reduction, process efficiency ...). And it would be nice if there was a one to one correspondence between actuation and effect - but there are other side effects. This is another reason for a strong experimental effort, with definition of a viable control structure as the final goal.

Considerable data has already been obtained from many of the diagnostics described in this work. These measurements have contributed to the establishment of the data base upon which the control scheme is being developed. Examples of this work have been described in other submissions from DIAL personnel (see references).

ABSTRACT

Thermal treatment (e.g. incineration) of combustible wastes provides a high reduction of volume and yields residues suitable for conditioning, transport and disposal. A variety of thermal treatment concepts has been tried throughout the world. Scientific and Industrial Association "Radon" uses on industrial scale excess air incineration and slagging incineration also. Now a new concept of thermal treatment (e.g. thermochemical treatment) of waste is under development at SIA "Radon". Investigations were done on thermochemical treatment of wastes by using special powder metallic fuel of very low off gas production. Thermochemical treatment involves chemical destroying of the organic portion of wastes as in conventional incineration. The main advantage of new fuel is its reduced gas production as well as involving of waste water and other components in chemical reactions. As result very high efficiency occurs for treatment process particularly for humid waste. non complexity of equipment is also an advantage of new treatment process. Powder metallic fuel consists of aluminum, magnesium and aluminum-magnesium alloy with some technological additives. It provides heat release 25-27 MJ per kg. Products of fuel oxidation are non volatile. Actual gas production consists only 17-55 liters per kg of fuel. Duration of treatment process is 1-2 hours, after this the ash is discharged for conditioning and/or disposal. Gas purifying system operate in the regime much softer than at conventional incinerators due to redox reactions between fuel and off gases particularly acidic components.

Preliminary tests were performed on the treatment of low level simulated radioactive waste. Their specific radioactivity was lower than 10 kBq per kg. Ion exchange resins, paper, wood, etc. were burnt. Biological active waste such as animal's cadavers were treated in field conditions. Practical complete incineration occurred. A mobile installation will be designed for the incineration of organic radioactive wastes on the base of these investigations.

INTRODUCTION

The necessity of thermal processing of mixed waste (containing both organic and non-organic harmful substances as well as radioactive nuclides) leaves no doubt due to their biological, chemical and radioactive danger. The danger for man and for the environment can increase with time because of the decomposition processes in the organic components of the waste and a possibility of spontaneous fire. In the latter case the danger is not only in the fire itself, but also in the combustion products, the most harmful among which are radioactive aerosols.

The technique of thermal decomposition leads to a considerable reduction of waste in volume and obtaining of fire-safe product. Due to the destruction of chemically complex components of the waste and the obtaining of simple oxides as the end result, the product of the thermal processing has minimal biological and chemical activity. At the thermal

treatment the majority of radionuclides remains in solid phase products, thus making it easy to locate them for further conditioning and burial. The process of the thermal decomposition of the waste can be realized in a number of ways. Among the most developed ones one can note the processes of burning with excessive oxygen, pyrolysis, shaft furnace treatment, plasma processing, the treatment in a shaft furnace with plasma burners for melting the ash residue, etc. (1,2). All the techniques for burning organic radioactive waste are characterized by a large amount of gas, therefore the majority of the burning devices form the gas cleaning system.

Within its activities SIA "Radon" has come across the necessity of treatment small quantities of combustible radioactive waste collected at sixteen Specialized centers of the system "Radon" (3). This was the aim of developing a technique and a mobile unit for burning radioactive waste with a capacity of 20-30 kg/hour. The fact that the unit should be mobile requires the burning technique to have low gas emission and a low chemically toxic components content in gases.

THE CHOICE OF BURNING METHOD

Usually an additional absorption of heat is required for burning waste. It is obtained by burning gas or liquid hydrocarbon together with the waste. When the fuel burns, resulting gases transfer the heat to the waste. A large amount of fuel is needed for burning waste, on average 0.25 kg of liquid oil products per 1 kg of waste (2). If kerosene, solar oil, or furnace fuel is used as fuel, 14.6-14.8 kg of air is required for a complete combustion of 1 kg of waste. 15.5-15.8 kg of gaseous products (carbon oxide, water) are obtained as a result, as well as approximately 0.1 kg of solid phase products in the form of ash. As a result, the amount of heat taken away by outgoing gases is much greater than the amount of heat remaining in the solid product. Now we must remember that the fact that the heat is taken away by gases is not a favorable process, it becomes clear that the thermal processing with the help of hydrocarbon fuel is very inefficient not only from the point of view of the complexity of gas purification, but also energetically wasteful.

In reality the production of outgoing gases during the thermal processing of the waste is not an indispensable characteristic of the process, and it depends on the method of its realization. First of all it is necessary to choose the fuel so that the end products of the combustion were non-volatile even at the temperature of the process. If fuel is chosen successfully, it is possible to have some of the lightly volatile products of the waste destruction interact with the fuel and also remain in a solid phase. The most successful for this purpose today are small off gas metal fuels - powder metal fuel based on aluminum and magnesium blends.

THE CHARACTERISTICS OF POWDER METAL FUEL

The powder metal fuels (further PMF) have been created on the basis of technological blends produced in Russia on an industrial scale. These blends are designed for contact heating objects with humidity of various degrees. The content of PMF is shown in Table I.

Table I

The PMF has a bulk density of 0.5-0.6 kg/dm3. It is chemically and physically stable, hit-proof, with the self combustion temperature of 500C. The PMF has a high porosity, approximately 50 - 60%.

The main combustion products of the PMF are aluminum and magnesium oxides. At the combustion of the PMF the main products is solid slag,

approximately 99.2 wt.%. The gas phase carries away only 0.8% of the mass of the burning products, leaving almost all the energy of chemical reactions in the solid phase. The air stoichiometrical coefficient of PMF is 3.15 kg/kg. At the same time, since the components of the PMF react with water, the water stoichiometrical coefficient is 1.2 kg/kg. The heat release of PMF is within 25 - 27 MJ/kg. Since the gas productivity of the PMF is small, the heat is transferred from the fuel to the waste by contact heating.

It is important to note that magnesium and its compounds are not harmful. The same is true for aluminum. Moreover, they are only slightly soluble in water. As a result, the combustion products of the PMF are safe for the environment. The fact that the PMF forms a compound with gaseous products of the combustion of organic waste, such as CO_2, SO_2, CO, NO_2, NO, reduces the influence on the gas purification system. This partially solves the problem of trapping harmful components which result from burning, as well as reducing the corrosion of the equipment. The interaction of both metals with water is favorable for burning damp waste.

COMBUSTION OF POWDER METALLIC FUEL

When burning the PMF the most important reactions are oxidization of metals which take place in a diffusion controlled regime. At the same time the burning of the PMF, unlike, for example the burning of termite welding mixtures is slow. The burning time of PMF can be between 7 and 45 minutes depending on the type of feed for the oxidizer.

The process of burning the PMF can be theoretically divided into two stages: the oxidization by own oxidizer and the oxidization by oxygen from the air.

The PMF includes potassium nitrate or sodium saltpetre, which acts as own oxidizer at the initial phase of the burning. This stage is short, 20-30 seconds. During this stage the metals in the fuel burn in the oxygen which resulted from the decomposition of nitrates. The process of the decomposition of nitrates of alkaline and alkaline-earth metals takes place in three stages: at first nitrate decomposes into nitrite: $2NaNO_3=2NaNO_2 + O_2$. After this the nitrite is decomposed into oxygen and peroxide: $2NaNO_2 = Na_2O_2 + O_2$. Finally peroxide decomposes, forming oxygen: $Na_2O_2 = Na_2O + O_2$. Using as fuel the energetic reducing agents Mg and Al a deeper decomposition of nitrite may take place: $Na_2O + Mg = MgO + 2Na$ + 44 kkal (174 kJ). This is accompanied by heating the PMF to temperatures 400 - 450C, which is necessary for the steady burning of the fuel in the oxygen from the air.

At the second stage of the burning the components of the PMF are oxidized by oxygen and water steam. This stage, depending on the conditions of burning, lasts 10 - 45 minutes. Since the reactions are diffusion controlled, the time required for this process greatly depends on the scale of burning. The process starts at a temperature of 400C, then the temperature increases to the temperature of burning the aluminum. The main compounds formed during this process, are AlN, Al_4C_3 and MgO at a ratio of 1:1:1. When the melting of aluminum is finished, the majority of oxides are Al_2O_3 and MgO.

The diffusion of gaseous components through PMF's pores and the diffusion of oxygen through the films of oxides appearing on the surface of the fuel's parts limit the speed of the process. However, as temperature rises, the evaporation of components is possible. The MFP burning process

can be easily controlled by supplying air into the area of burning. In this case temperature varies between 800 and 2500C.

EXPERIMENTAL UNIT

An experimental stand was constructed to test new technological process of waste burning by using PMF. This stand contains a vertical multi-sectional furnace with a diameter of 400 mm.Each section of this furnace is 400 mm height, the furnace having 1 - 4 sections depending on required productivity (see Fig. 1). Smaller netted drums with the diameter 350 mm were used to maintain waste inside of each section. These small drums were filled preliminary by waste-PMF mixture. The sections were installed on the stand, after this charged by filled (or empty) drums. The last section was connected to gas purifying system.

Fig. 1

The gas (air) inlet is located on the bottom of furnace, the inflow of air from tightness of furnace being negligible. Typical simulated radioactive and non radioactive wastes were used in experiments: paper (dry and damp), wood, cleaning cloth, PVC and ion exchange resins. In some cases this waste was preliminary prepared for experiments, for example PVC was shredded before loaded.

Special attention was given to the thermal destruction of wet ion exchange resins based on a polystirol matrix, containing up to 50 wt.% of water. The level of contamination due to presence of Cs-137 was not higher than 10 kBq/kg. The discharging of furnace was provided by dismantling furnace and removing netted drum with ash residue.

EXPERIMENTS

The purpose of a number of experiments done at the experimental stand was to determine the appropriated method for loading furnace (netted drum) with the PMF and waste, their proportions and mode of burning initiation. As the result it was selected the method when a layer of the PMF 0.5-1 cm thick is put on the lower fire bar grate, followed by a layer of waste about 10 cm thick, then another layer of the PMF, and so on, with the top layer in the section being the PMF. The proportion between PMF and waste was chosen within 0.15 - 0.20. The combustion process was started with initiating the bottom layer of the PMF. The average chemical formula of fuel was Mg30.35 Al8.99 C0.712 H1.148 K0.098 N0.098 O0.03.

It was established that combustion process go in two regimes depending on the air supply. When air is lacking, there takes place the burning of the PMF and the pyrolysis of the waste immediately near to the fuel layer. The pyrolysis gases do not burn. This regime leads to the process fading away, as the burning does not spread over the whole furnace. When a required portion of air is supplied, a controlled spreading of burning over the whole furnace takes place. In this case some amount of pyrolysis gas burns when mixing with the air inside the furnace. The burning process here can be divided into two stages: the pyrolysis and coke formation stage and the coke burning stage. During the pyrolysis stage the drying, pyrolysis of the organic materials and the burning of the pyrolysis gases take place. This stage is characterized by the formation of a large amount of burning gases. As the waste decomposes and coke is formed, the burning comes into the next stage. During the coke burning stage, the coke burns forming CO2 and ash. When the air is excessive all the processes are accelerated and higher temperatures are achieved.

The combustion process from the initiation of burning up to discharging of ash residue lasts 1 - 2 hours. The temperature in the furnace during

combustion took a value up to 1150oC, average temperature being between 850 - 1000oC.

RESULTS AND DISCUSSION

Complete destruction of organic part of waste was achieved in all experiments. The incomplete combustion (non organic) in the ash residue in different experiments was between 0 and 10wt.%. Radionuclide release directly from furnace during experiments has been not higher than 18%, usually being lower than 5%. The productivity of furnace was estimated to be about 10 kg/h per section for ion exchange resins Specific capacity in this case was about 80 kg/m2h.

The results of analysis of exhaust gases formed during the combustion of wet ion exchange resin are shown in Fig. 2.

Fig. 2

The analysis of ash-slag residue was performed by using X-ray difractometer (DRON-2) and scanning electron microscopy (REMMA-202). The following phases were found in the slag: MgO(main products), spinel $MgAl_2O_4$, a small amount of nitrides AlN, Mg_3N_2, the aluminum and magnesium alloy as non burnt fuel, Al and K_2CO_3. Besides, there was detected MgOHCl as a result of Cl trapping from off gases.combustion in field conditions

Other experiments were carried out in field conditions without special equipment for the combustion of non radioactive biological dangerous waste. Many experiments have shown that it is necessary to use not less than (0,40 - 0,45) kg of oil products per 1 kg of the biological waste in the field conditions (even during dry summer weather). The new feature when using the PMF for burning biological objects is that the system PMF + biological object, accordingly to thermodynamic calculations, burns even without air due to the exothermic reactions of proteins, fats and water with metals in the PMF at temperatures up to 1100-1500 K. Moreover, the presence of excess air leads to an increase in temperature of up to 3100 K.

A no-equipment method of combustion biological objects in field conditions has been developed. In accordance with this method a trench of a volume approximately equal to the volume of the biological object is dug in the place where the biological object is found. Taking into consideration the direction of air, special air pipe trenches are dug up to the trench. A 1-2 cm layer of the PMF is spread over the bottom of the trench. The biological object is placed in the trench, after this 1 - 2 cm layer of the PMF is also put on top of the biological object. The proportion waste - PMF is 0.2 wt. The combustion process after the initiation of burning takes place without any interference from the operator. Duration of complete combustion is 5 - 6 hours for a 100 kg biological object.

CONCLUSIONS

A new concept of thermochemical treatment of waste is under development at SIA "Radon". This concept is based on applying a new sort of fuel to maintain incineration of various waste. The main advantages of new fuel are: its reduced off gas production, heavily heat transfer, involving of waste water and other components in chemical reactions. As result very high efficiency occurs for treatment process particularly for humid waste. Preliminary investigations on thermochemical treatment of waste by using special powder metallic fuel of very low off gas production demonstrated challenging feasibility of this method.

A METHODOLOGY FOR ASSESSING RECYCLING AND DISPOSAL COSTS ASSOCIATED WITH SURFACE CONTAMINATED SCRAP METAL

Anthony Kluk
U.S. Department of Energy

J. Wynn Phillips
James Culp
Analytical Services, Inc.

ABSTRACT
Decommissioning and demolition of facilities or the discontinuation of some programs has left the Department of Energy (DOE) with radioactively contaminated scrap metal some of which is potentially recoverable or recyclable while the rest requires disposal. While there is pressure within DOE to conserve resources and recycle scrap metal, there is also a demand that actions be cost effective, and it is often whether recycling is economically viable. This problem is increased by the lack of a consistent approach to making appropriate cost comparisons and by changing market and other variables.
This paper, based on an report in preparation, addresses this issue as it relates to surface contaminated scrap metals, especially carbon steel. More specifically the report attempts, in some ways, to standardize and facilitate the cost analysis process and analyzes the sensitivity of various cost factors. A series of graphs are included which facilitate the analysis of costs associated with the survey, decontamination and recycle of surface contaminated scrap metal and allow comparisons of these factors to the cost of sizing, packaging, transportation, and disposal of those metals. The graphs have been developed to cover the range of costs covered by these elements. The range of costs were identified using data in the literature and actual costs incurred at DOE sites that are decontaminating metal for free release and are compared to data from sites currently disposing of radioactively contaminated scrap metal.
The graphs facilitate analysis of the effects that various cost elements have on the overall cost. If the total cost of recycling exceeds the cost of disposal, the graphs can be used to determine areas requiring cost reductions necessary to achieve comparability with the cost of disposal. Cost elements include 1) costs for preparing the metal for transportation; 2) options for purchasing or renting a variety of

containers that could be used for recycling; 3) transportation costs, including transportation of metal that cannot be decontaminated and secondary waste from the decontamination process; 4) decontamination costs; and 5) disposal costs, including disposal of metal that cannot be decontaminated and secondary waste from the decontamination process. Transportation costs have been simplified so that estimates may be calculated knowing only the distance or the weight of the metal to be transported. Disposal costs are based on costs currently charged by disposal sites, both DOE and commercial, and expected future costs at new disposal facilities. Decontamination costs are per pound costs based on vendor quotes provided to various DOE sites and in published vendor data. Other variables that may be assessed for their impact on the overall cost of either option include the percentage of the surface requiring decontamination, the percentage of the metal that can be decontaminated to free release guidelines, the cost of surveying the metal and that of truck or rail transportation, the distance to the disposal site or decontamination facility, the quantity of secondary waste generated and the cost of burial.

SUMMARY AND CONCLUSIONS

Based on the case developed in this paper using parameters reported by DOE sites, it is evident that there are two major factors in determining whether to decontaminate and recycle structural steel or to package it for disposal. These are the cost of decontamination which is roughly 63% of the total cost of recycling and the burial charge which constitutes more than 56% of the total cost of disposal. Chart 1, Recycle Option Costs and Chart 2, Disposal Option Costs (Fig. 1), show appropriate relative percentages of the various cost elements for the case used in this study.

Fig. 1

Based on the costs used in the sample case, the break even cost for disposal (at a decontamination cost of $0.76 per pound) is about $23 per cubic foot. Of the DOE sites currently accepting waste from other sites, all charge more than $40 per cubic foot, except the Nevada Test Site (which is less than $20 per cubic foot). Therefore any decontamination process that costs less than $0.76 per pound would be cost effective for sites that do not use the Nevada Test Site for disposal.

COST COMPARISON METHODOLOGY FOR MILD CARBON STEEL

The data presented below can be used in conjunction with Figs. 2 through 11 to estimate and record specific costs associated with the recycling of mild carbon steel versus those associated with disposing of the same material as waste. Descriptions of how each graph is to be used are presented below. Costs estimated from the figures should be recorded and totaled in Table I. The values in the table are from the sample case. Log-log scales are used so when interpolating between two lines the mid-point between them represents a cost about 70% of the way between the lines.

Based on the size and type of container to be used, select the appropriate line from Fig. 2 of Graphic 1. Draw a horizontal line from the total weight of metal being analyzed to the line which represents the container to be used and the weight of metal to be shipped in each container, i.e., the net weight of contents. This is point P-1. It identifies the number of containers needed for the quantity of metal to be shipped. Extend the horizontal line through Figs. 3 and 4 in Graphic 1. From intersection point P-1 draw a vertical line to determine the

number of containers needed. Extend this line down through Figs. 5, 6 and 7 in Graphic 2. If different containers are being considered for disposal and recycle, two values will have to be determined.

Fig. 2

Fig. 3

Fig. 4

If the weight of metal that will be placed in each container is not known, but the bulk density of the metal in the package is available, multiply the bulk density by the interior volume of the container to get the weight of metal in the container. Be sure to check this weight with the capacity of the container, and use the smaller of the two numbers to prevent overestimating the amount of metal that can be shipped in a given container (specific containers are certified for a specific gross weight). If a given container has two weight limits (depending on its use as a strong tight container or a DOT approved 7A container) and the weight of metal in a container falls between the two, use the larger number and the appropriate cost for that container. (See Table II on Graphic 1 for container weights and allowable weights of contents.)

The on-site preparation cost is the sum of the surveying, sorting, sizing and loading costs for a particular project. Find the appropriate line on Fig. 3 in Graphic I which best approximates this total cost per ton of metal and label the point of intersection with the horizontal line for the weight of metal to be dispositioned as point P-2. Draw a vertical line from point P-2 to find the total on-site preparation cost. If site policy calls for different degrees of preparation related to any of these activities (i.e., a more detailed survey for disposal vs. shipment to an NRC licensed decontamination facility, or more sizing to get the material into smaller shipping containers for disposal) then two values should be determined, one for disposal, C1D, and one for recycling, C1R. Enter these costs in Table I.

The cost charged to decontaminate metal for recycling is negotiated between the DOE site and the vendor who provides the service. Typical costs range from fifty cents per pound to slightly over a dollar per pound. Under some circumstances this cost may include the cost of transporting the metal to the vendor in which case a separate transportation cost would not be charged.

If all the metal requires decontamination, find the average decontamination cost line on Fig. 4, in Graphic I, or approximate between lines, and the intersection of this line with the horizontal line for the weight of metal to be processed. This is point P-3. Draw a vertical line to the lower axis to find the total decontamination cost, C4R. Enter this cost in Table I, under the Recycle column only.

In the event that a significant fraction of the metal will not require decontamination (i.e., already meets release guidelines), it may be cost effective for the vendor to survey all the metal prior to decontamination. While this would increase the processing cost for the contaminated metal, it could lower the overall cost by avoiding decontamination of already clean metal. Based on data for survey costs it is estimated that the additional survey could cost between $0.015 per pound and $0.10 per pound of contaminated metal. Handling costs for container unloading, movement of the metal onsite and delivery to a central pickup point are estimated to add an additional $0.10 per pound to the cost for surveying only. Therefore, if a significant fraction of the metal does not require decontamination, the vendor cost for

processing this metal could be approximately $0.20 per pound while the cost to decontaminate could increase by $0.10 per pound.
If only a fraction of the metal will required decontamination, add $0.10 per pound (worse case) to the average decontamination cost, find this cost line on Fig. 4, in Graphic I, or interpolate. The intersection of this line with the horizontal line for that fraction of the total metal weight to be processed is point P-3A. Draw a vertical line to the decontamination cost, C4Ra. Enter this cost in Table I, under the Recycle column, Decontamination Cost.
For the remaining fraction of the metal, draw a horizontal line from the weight of this metal to a unit cost line representing the cost for surveying and releasing only. This is point P-3B. Draw a vertical line down to find the decontamination cost, C4Rb. Enter this cost in Table I, under the Recycle column, Survey Only Cost.
Fig. 5
Fig. 6
Fig. 7
Table I
Table II
Starting at the number of containers calculated from Fig. 2, enter Fig. 5, on Graphic 2, and draw a vertical line to the container cost. This is point P-4. Draw a horizontal line from P-4 to the vertical axis to determine the total container cost. Enter the cost, C2D, in Table I, under disposal.
Starting with the number of containers for disposal, 1D, and recycle, 1R, draw a vertical line to the graph(s) which represents the type of container to be used and the weight of metal to be shipped in each container in Fig. 6, on Graphic 2. A horizontal line to the vertical axis will determine the number of shipments required to ship the metal. These are points P-5D (disposal) and P-5R (recycle) and will be used later to determine transportation costs.
Again, starting with the number of containers identified in Fig. 2, enter Fig. 7, on Graphic 2, at that point and determine the total burial volume of the containers used for disposal. This is point P-6D, and will be used in Fig. 9, on Graphic 3, to determine disposal costs. The line on this graph for drums should be used in assessing the cost of disposing secondary waste generated as a result of metal decontamination activities. A line for SeaLand type containers is not included since they are normally not used for disposal.
Fig. 8
Fig. 9
To determine the transportation costs for disposal and recycle it is necessary to estimate the cost of a single shipment. This is primarily a function of the transportation distance.Generally speaking an average cost of $1.43 per mile or $0.04 per pound (including the weight of the container) can be used. Using the number of shipments for disposal, 5D, and the number of shipments for recycle, 5R, enter the figure at these points and draw a horizontal line to the appropriate per shipment cost. A vertical line to the horizontal axis will identify the transportation costs for disposal, C3D, and for recycle, C3R. Enter these costs in Table I for transportation. The recycle option contains a second transportation cost which is related to the cost of transporting secondary waste to a disposal site. This cost will be calculated later.

Using the burial volume for the disposal option from Fig. 7, identify the line in Fig. 9, on Graphic 3, which is closest to the unit burial cost, $/ft3, for the site where this material would be buried. Based on a specific burial cost, $/ft3, identify the total burial cost C6D, and enter this cost in Table I, in the Burial column.

Fig. 10

Fig. 11

These figures are used only for the recycle option when containers for the transportation of the metal to the decontamination facility are leased for the duration of the project. Figure 10, on Graphic 4, should be used when the transportation distance is short enough that the turnaround time for a shipment, including the time to fill the containers and load them on the truck is one week or less. Figure 11, also on Graphic 4, is based on a turnaround time of two weeks. Using the appropriate figure enter at the weight of metal to be handled and draw a horizontal line to the graph which represents the type of container to be rented and the weight of metal that would be shipped in each container. From this point draw a vertical line to the total rental cost, C2R. Enter this cost in Table I.

SECONDARY WASTE

The generation of secondary waste during decontamination is a consequence of the decontamination process. Some of this waste may be considered as generated by the vendor providing the service. In this case the vendor is responsible for material disposal and its cost will be reflected in the price of the service being provided. Other wastes, which can be identifiable as resulting from activities relating to metals from a DOE site, including disposable workers clothing, wipes, solidified chemical solutions, laboratory waste (wipes, swipes, etc.), and any metal that cannot be decontaminated, are the responsibility of the originating DOE site.

Once the quantity of secondary waste has been determined, Fig. 2 and Figs. 5 through 9 can be used to determine the costs associated with the purchase of burial containers, the transportation of the containers to a disposal, and the cost of disposal following the steps presented above. If the soft wastes (clothing, wipes, etc.) are to be packaged in boxes along with the metal scraps and pieces that can not be decontaminated, then the disposal costs for these materials can be determined as a percentage of the metal to be decontaminated, typically about 2% by volume. Follow through the graphs as previously instructed to obtain costs associated with containers (enter this cost in Table I as Item C2RD); the cost associated with transporting these materials (enter this cost in Table I as Item C3RD) and the cost associated with the disposal of this waste (enter in Table I as Item C5RD).

All cost data as tabulated in Table I can be summed and the totals compared.

SAMPLE CASE

A sample case has been developed using the following input:

Total weight of metal to be handled (recycled or disposed) is 2,000,000 pounds, or 1,000 tons.

The on site preparation cost is $100/ton for recycling and $70/ton for disposal due to more stringent acceptance criteria at the recycling facility than at the disposal facility.

In both cases B-25 boxes will be used for transportation of the material. Each box will be filled with 4,000 lbs of steel, equivalent to the use of a B-25 box as a strong tight container.

The purchase price of a B-25 box for disposal is $425. B-25 boxes are leased from the decontamination facility for transportation and the shipping distance is far enough that container turn around will take approximately two weeks.

Per shipment transportation costs were as follows:

To the decontamination facility - $500.

To the disposal facility - $1000.

Secondary waste from the decontamination facility back to the originating site and then to disposal - $1500.

30% (600,000 pounds) of the metal is believed to not require decontamination and will be surveyed for free release at a cost of $.20/lb. A decontamination cost of $0.76/lba has been assumed with an additional cost of $0.10/lb for a pre-survey to identify metal which does not require decontamination.

Disposal of the metal as waste will occur at a DOE facility at a cost of $20/ft3. Ten percent of the original weight of the metal will be disposed of as secondary waste and it will be disposed at the same site. Other secondary waste generation is assumed to be small (roughly 2% by volume) and not significant.

The results of this case are presented in Table I.

While the disposal option in this case is less expensive than recycling there are several factors that could easily change the economics. Some of these factors can be identified as follows:

1) Burial Cost: With a cost difference of roughly $282,000 and a difference in volume of material to be buried as waste of 45,000 ft3, an increase in burial cost of slightly more than $6/ft3 would make disposal more expensive. $20/ft3 for disposal is consistent with current charges at NTS. An increase to $26/ft3, which is significantly less than the current disposal cost at many of the other DOE sites such as Hanford, Savannah River, Idaho or Oak Ridge, would make recycle the less expensive alternative.

2) Decontamination Cost: Again, with a cost difference of $282,000, the decontamination cost would have to drop by approximately $0.20 per pound ($282,000/1,400,000 pounds; 70% of the 2,000,000 pounds requiring decontamination) for the recycling option to be more cost effective than disposal at a disposal cost of $20.00/ft3. Recycling would also be competitive with disposal (at $20/ft3) if only half of the metal required decontamination and the other half could be released after survey.

3) Use of SeaLand Type Containers: At 40,000 pounds net weight of contents, 2,000,000 pounds of metal can be transported to a decontamination vendors facility in only 50 shipments at one container per shipment compared to 500 B-25 boxes each containing 4,000 pound of metal. The use of B-25 boxes would also require 50 shipments of ten boxes each. However savings could be realized in lower rental costs for the container and lower packaging costs since less sizing of large pieces is required.

ABSTRACT

BNFL has almost completed the decommissioning of a major nuclear enrichment facility in the UK - the Capenhurst Diffusion Plant. This massive facility, 1,200m long and 150m wide and housed under a single roof, consisted of a cascade of 4,800 'stage units' of various sizes connected by 1,800 km of process gas pipework.

Dismantling the plant yielded over 160,000 tonne of suspect surface-contaminated material. By the time the project is fully completed, around the middle of 1996, over 99.5% of the contaminated material will have been safely and cost-effectively treated such that it can be recycled for unrestricted use in a non-nuclear environment. The remaining material, as well as minimal quantities of secondary wastes arising from decontamination activities, will have been size-reduced and/or encapsulated to maximize the cost-effective use of the UK low level waste burial facility at Drigg.

Although a number of novel and specialized techniques have been developed for use in this project, maximum use of "off-the-shelf" equipment, customized as necessary, has resulted in total project costs below 100M; i.e. in the order of 600 per tonne of material processed.

The project has utilized a wide variety of size-reduction measures, including robotic plasma cutting, novel decontamination techniques, melting for high and low melting point metals, and incineration of non-metallic arisings. The project has also met the challenges posed by the need to accurately and cost effectively measure very low activity levels after decontamination in order to confirm that the UK criteria for unrestricted release of material into the external market have been met.

All activities have been performed without compromising environmental discharges, the safety of plant operators, or the general public. In particular the personnel involved with the exercise have received confirmed radiation exposure levels of less than 0.2 mSv/yr.

INTRODUCTION

The Capenhurst Diffusion Plant was built in the early 1950s at which time it was the largest industrial building in Europe under a single roof, (Fig. 1). Some 1,200m long and 150m wide, the plant consisted of a cascade of 4,800 "stage units" of various sizes connected by 1,800 km of process gas pipework up to 550 mm dia, with numerous valves and associated process services (Fig. 2).It was originally built to produce highly enriched uranium for defence purposes but in the early 1960s the high enrichment section was isolated, emptied and put under care and surveillance. The rest of the plant was then modified to produce low enriched uranium for civil use.

Fig. 1

Fig. 2

By 1982, URENCO centrifuge enrichment plants were operating successfully at Capenhurst and the no-longer economic Diffusion Plant was shut down. As has previously been reported (1), a decommissioning project was begun to deal with over 160,000 tonne of suspect surface contaminated metal, concrete and other potentially hazardous materials. The significant nuclides involved in the contamination were Uranium and its daughter products, together with Technetium 99 (Tc99) and Neptunium 237 (Np237) from re-enrichment of reactor-recycled uranium. By the end of 1995, less

than 1% of the total mass of materials arising from this project will have been consigned for burial as low level waste. Over 99% will have been successfully treated and recycled. Less than 725 tonnes will have been despatched for land burial.

DECOMMISSIONING PHILOSOPHY

The main aim of this project has been to recycle as much of the above material as possible for unrestricted re-use, while minimizing the impact on the environment and the dose commitment to the workforce.

It was recognized from the outset that a significant 'up-front' investment would be required to develop suitable techniques to achieve this aim at minimum cost. The first two years of the project were therefore focused on research and development into cost effective decommissioning techniques, looking outside the nuclear industry for off-the-shelf equipment which could be used to meet the project needs without 're-inventing the wheel'. Figure 3, which represents the culmination of this exercise, identifies the activities involved in decommissioning the Capenhurst Facilities in the form of a process flowchart. The R&D investment has also left BNFL with the expertise needed to design, procure, operate and maintain specialized decommissioning plant and equipment of this type.

Fig. 3

SPECIALIZED TECHNIQUES

Plant Pre-treatment

Before the Diffusion Plant was shutdown, exploratory test work provided radiological and criticality data for subsequent use. A fluorination process was then employed to convert solid deposits within the plant to volatile fluoride compounds which could be safely disposed of. With the plant at standstill, further local operations dealt with any significant remaining pockets of solid or gaseous contamination.

Plant Dismantling

The main dismantling task was to break down the process plant into manageable units, many of which were then stored pending the availability of size reduction and decontamination facilities. Economical methods for safe penetration and in-situ cutting were developed. Units were then removed, sealed and placed into managed outside storage of up to 7,000 tonne of material.

Much of the main buildings, with the cells which had originally housed the plant and ancillary structures such as eleven cooling towers, pumphouses and an electrical substation, were demolished, monitored and sold as clean scrap. Floor slabs were decontaminated, ground samples checked and confirmed to be free from contamination, and the area returned to greenfield status. Stage units, ranging from smaller 750 kg steel shells to aluminum fabrications weighing 7 tonne and occupying 27m3, around 200,000 lengths of piping. 3,500 tonne of electric motors and 800 tonne of process valves were removed and treated.

Size Reduction

When removed from the plant, most items were too large and complex to be monitored or decontaminated without cutting. For each type of item, a cutting plan specified how to dismantle it further and, for wet decontamination, how to fill the baskets used in the decontamination equipment so as to expose all surfaces to the cleaning liquors. Most cutting was repetitive and was therefore automated using dedicated equipment installed in disused areas of the Diffusion Plant. A wide

spectrum of cutting options was examined and the most appropriate selected for each case.
The following examples show some of the varied size reduction techniques used.

Robotic plasma cutting - The size and complexity of the 750 aluminum stage units posed particular problems. After studying all the available options it was decided to develop a facility based around two large industrial robots adapted for plasma arc cutting. A special ventilation system, which dealt with the large volumes of fume generated, and fully remote operation minimized operator exposure. This type of flexible automation is available for future work (Fig. 4).
Fig. 4

Remote gas cutting - 1,400 of the nickel plated steel stage units were cut up using semi-automatic gas cutting, again using special ventilation and remote operation.

Large bandsaw - 2,200 tonne of aluminum pipework up to 450 mm dia was satisfactorily size-reduced using a large capacity bandsaw with rollerbed feeding.

Tube trepanning and stripping - 2,500 heat exchangers contained a total of 98,000 uncontaminated cupronickel tubes sheathed with contaminated aluminum fins. Special equipment was developed to trepan the tubes out of the tube plates and then strip the clean tubes away from the fins without cross-contamination.

Routing - Where hot cutting is inappropriate, routing is an economical alternative, again needing special facilities to contain swarf and minimize operator intervention.

Decontamination

The success of the project depended crucially on development of a decontamination process to remove surface contamination from a wide variety of metals and surface textures, ranging from bright wrought aluminum plate to heavily rusted steel. As noted earlier, the full range of nuclides resulting from handling reactor recycled uranium had to be removed, including Tc99 and Np237, the most obstinate sources of contamination.
Following extensive laboratory and pilot plant investigation, a full scale wet decontamination plant was developed, and finally completed in 1989 (Fig. 5). As probably one of the largest decontamination facilities in the world, it remains in operation capable of processing up to 100 tonnes per week. Suitable size-reduced items are loaded into baskets (nominally 2m x 1m x 1.5m) and then automatically pass through successive stages of washing in specially formulated process liquors which entrain the nuclides for subsequent transfer into ion exchange resins. The resins, which represent relatively small and manageable volumes of active residues, and other solid and liquid wastes of acceptably low activity and toxicity are later encapsulated in a cement matrix.
Fig. 5

Melting

Melting of low-level active metals has been reported in France (2), Germany (3), Sweden (4) and Japan (5) amongst others. The main aims have been towards products restricted for use within the nuclear industry, or for volume reduction prior to burial. By contrast, the Capenhurst melting facility primarily aims to produce ingots which are below free-release levels for unrestricted re-use. This is achieved by first decontaminating the feedstock as described above, and then using melting to produce

metals in a form such that they can easily be monitored to confirm the level of contamination is at or below free-release levels. Melting produces a homogeneous ingot, samples from which can be monitored to confirm for free release or sentenced for burial. In the latter case, there is still a value in reducing burial volume and in fixing activity within the ingot.

Following pilot trials, a full scale melting facility was developed and installed (Fig. 6) to process a range of contaminated metals, including items with non-metallic additions. Aluminum, lead, copper, bronze, cast iron, steel and nickel have all been melted, and it has been possible to separate lower melting point metals from higher melting point metals. Non-metallics have been incinerated with full environmental protection.

Fig. 6

The facility, which has a throughput up to 150 tonne per week, is a controlled active area with full radiological engineered safety systems. These include a highly sophisticated fume cupboard and treatment system which removes all particulate and volatile radioactive and toxic substances in strict compliance with Environmental Protection Regulations. A facility control system, including dual redundant programmable controllers, ensures safe shutdown of the facility on detection of any excursion from defined limits, thus minimizing the risk of personnel dose uptake and preventing undesirable environmental discharges.

Special attention is given to determination of the radioactive content of the ingots which are at levels close to those occurring naturally. Radiochemical determination involves dissolution of samples of a few grams weight, extraction of the nuclides and counting by liquid scintillation. Detection limits are 0.1 Bq/g, but the method is relatively expensive. Delayed neutron counting is cheaper, but requires a 'fingerprint' of the isotopic ratios - not a consistent parameter within the Diffusion Plant. The more costly techniques have been used to calibrate a low level alpha/beta counter which is used to determine the activity within disc specimens (60 mm dia and 6 mm thick). Due to the low background level of this counter, less than one count per minute, and the ability to count up to ten discs simultaneously, count times of about one hour gave the required accuracy, and large numbers of samples can be processed at low cost. It is necessary to exert close control over sampling and counting techniques to avoid cross-contamination.

The initial campaign treated around 4,000 tonne of metals which were decontaminated to relatively low levels of contamination. They still could not be released, however, because their complex geometry prevented full monitoring. Examples include small bore pipework never exposed to process gases, closed voids within weldments, and re-entrant surfaces generally. Following successful demonstration of the containment of contamination within the melting facilities, a justification has now been made to extend the capability of the facilities to process metals contaminated at higher levels. Data is also available on the degree of partitioning achieved during the melting process.

Encapsulation of Waste

The small volume of waste destined for land burial comprises both solid metals and a variety of less easily packaged materials. These included secondary waste such as evaporated process liquors, ion exchange resins, melting drosses and slags, filter media, swarf and floor sweepings. A skid mounted, transportable encapsulation plant has been designed by BNFL

and is in operation at Capenhurst. This plant immobilizes the wastes into an ideal non-leachable form for low level waste disposal at Drigg using a specially formulated cement encapsulant in standard 200 liter drums.

RECYCLED MATERIALS AND WASTE STREAMS

Solid Arisings

Once plant contamination has been characterized, it is essential to define the waste streams for which process routes will have to be established, and with which all other decommissioning decisions will have to be consistent. It is then necessary to identify the disposal options for the original contaminated material as well as any secondary waste streams arising from the process routes utilized.

Unlike most other countries, the UK has clearly established criteria for unrestricted release of material into the external market. The criteria exempt substantially insoluble solids with specific activity below 370 Bq/kg of any nuclide, with additional exemption for uranic activity below 11,100 Bq/kg. Whilst international rationalization of clearance levels may ultimately lead to a more nuclide-specific set of release criteria, with higher limits for soft beta emitters such as Tc99, the timescale for such legislation is likely to be extended and the operations at Capenhurst needed to be carried out in line with the more restrictive application of the current regulations. The development of cost-effective techniques to confirm the criteria are met has also been a very important consideration for melted ingots.

The only available disposal option within the UK for materials exceeding the criteria for unrestricted release is land burial at Drigg, the BNFL Low Level Waste Disposal Site near Sellafield. Burial of large volumes of contaminated material would have imposed massive cost penalties on the project, as well as occupying an unacceptable and unnecessary proportion of the valuable low level waste site capacity. Effective decontamination and sentencing of the maximum amount of material to free release levels was therefore highlighted as an essential part of the project.

Against this background solid arisings from the project have been categorized as follows:

Clean scrap - materials which can be proved by monitoring to be suitable for free release.

Metals for decontamination - metals which can be decontaminated and subsequently can be proved by monitoring to be suitable for free release.

Metals for decontamination and subsequent melting - metals which can be decontaminated but because of complex shapes/surfaces, cannot be economically or effectively monitored but which would be suitable for melting and recasting as ingots. After melting, the material would then be in a form capable of being monitored to confirm its suitability for free release.

Materials not suitable for free release - Material (the remaining small quantities of material including some secondary waste arisings) which is not suitable for free release and is therefore consigned for land burial.

Other Arisings

The main source of liquid waste is from the decontamination process and is subject to discharge authorizations covering radionuclides and toxic metals which limit discharge into local water courses to below 100 Bq/liter/day and to below 1.8 ppm total metals. Other liquid wastes up to 1,000 Bq/l are acceptable to the Regulators for landfill disposal.

Gaseous discharges are limited by the discharge authorization for the whole Capenhurst site to less than 50 MBq annually. Actual emissions are

less than 1MBq annually. A comprehensive routine sampling and analysis program exists to monitor and confirm environmental discharges. Compliance is further supported by regular audits by relevant Government Departments.

PROJECT SAFETY

An overriding concern throughout the project is to minimize risks of radiation exposure to decommissioning operators, personnel on site and the public generally. Alpha in air monitoring, with an alarm level set at 3 Bq/m3, is used extensively throughout the facility as is routine surface monitoring. A criticality detection system is installed, and strict criticality control procedures applied at every stage. Specialized workshops were constructed using redundant cells from the Diffusion Plant itself for the various operations with dedicated and effective ventilation.

Operators use personal air samplers, respiratory protection, and full protective clothing as appropriate, (Fig. 3) and the BNFL personnel radiation protection program has confirmed exposure levels at less than 0.2 mSv/yr. Full account is also taken of non-radiological hazards, particularly those associated with other toxic or hazardous materials removed during dismantling.

COST DRIVERS AND SAVINGS

The total cost of the project on a historical cost basis is less than 100M - in the order of 600 per tonne of material. About 20% of that total (representing a major investment), was applied to decommissioning R&D. Major costs drivers for BNFL included external purchases of hardware, costs of burial at Drigg, labor and charges for health physics and radio-analysis. The decommissioning of the Diffusion Plant will be completed within budget.

The following features all contributed to what will be a major achievement:

Early investment in identifying and categorizing the various wastes was vital in laying the foundation for well focused investment in specific decommissioning techniques.

Most importantly, the efficiency of wet decontamination avoided burial costs, and generated income from sales of metals for unrestricted re-use.

Where the shape or surface structure of cleaned metals did not allow cost-effective monitoring, melting, supported by cost effective techniques to confirm that the UK criteria for unrestricted release of material into the external market have been met, proved an ideal adjunct to facilitate further recycling.

Value engineering was used to good advantage through the project. Finally, the value of a well motivated, well trained and enthusiastic workforce contributed substantially to the successful outcome.

CONCLUSIONS

The philosophy and techniques described above are likely to be relevant to a wide range of nuclear processing plants throughout the world, particularly larger plants with low levels of primarily surface contamination.

The Diffusion Plant decommissioning program will be successfully completed by the middle of 1996.

Of the 160,000 tonne of metals and concrete comprising the structure and contents of the plant, over 99.5% will have been recycled for unrestricted re-use as clean material.

The project demonstrates how the Capenhurst Diffusion Plant, a major nuclear processing plant facility, has been safely and cost-effectively decommissioned.
The experience gained from this project has resulted in methodologies being developed to minimize the amounts of nuclear and other hazardous wastes arising from decommissioning activities and demonstrated cost effective techniques to confirm that the UK criteria for unrestricted release of material into the external market have been met.
The techniques developed can be applied to other nuclear or non-nuclear processes.

OECD/NEA
Co-operative Programme on Decommissioning
Nykping, Sweden

ABSTRACT

The recycling of contaminated material could be a major means of reducing the quantities of low level waste produced by the decommissioning of nuclear facilities. Both the European Commission (EC) and the OECD Nuclear Energy Agency (NEA) have been working on this subject during the last few years.
The European Commission has sponsored research and development on the reuse and recycling of low level solid waste materials originating from the decommissioning of nuclear installations, within the framework of three sequential five year research programs, the first of which started in 1979.
A series of R & D projects were carried out on the reuse and recycling of various materials originating from the refurbishing/dismantling (steel, copper, aluminum and concrete). Particular progress was made for the recycling of LLW steel, using the melt technique not only for volume

reduction but also for the production of specific items for the nuclear industry.

The EC has also set up, under the terms of Article 31 of the Euratom Treaty, a group of experts to examine the implications for radiation protection of recycled materials from nuclear installations with a view to establish appropriate recommendations for clearance levels. First recommendations issued in 1988 (Radiation Protection Series No. 43) relate to the recycling of radioactive steel. Further recommendations for metals, including copper and aluminum are under preparation. A similar document for concrete is intended. A task group set up by the OECD/Nuclear Energy Agency's Co-operative Programme on Decommissioning has been studying recycling during the last three years. It has noted that considerable material is being released from regulatory control today, but mostly on a case-by-case basis, with widely varying release criteria in different countries.

Both the EC recommendations for release criteria and those proposed by the International Atomic Energy Agency are essentially based on radiation protection considerations. The NEA task group has attempted to view recycling in a broader context, evaluating both radiological and non-radiological detriments as well as social, economic and environmental aspects. This is seen to be fully in harmony with the ICRP concept that the justification of a practice should take into account the total detriment and not only the radiation detriment.

This approach has led to the consideration of a tiered system of clearance levels, allowing a more rational material management, where release levels would depend on whether the materials were being released directly, sent for melting, melted in controlled facilities before release for remelting or reused for specific purposes etc.

Both the EC and the NEA see the need for internationally agreed clearance standards, specially when much larger quantities of material become candidates for release, when today's operating reactors come to the end of their useful lifetimes.

INTRODUCTION

Recycling of contaminated material has been identified as a major means of reducing the volumes of waste for ultimate disposal arising from the decommissioning of nuclear facilities. The incentives lie both in the huge quantities of contaminated material produced over a relatively short period of time as well as the steeply escalating costs of final disposal space in most countries.

The European Commission (EC) has, in a series of three five year programs, sponsored R & D projects in this area, through shared costs contracts with various organizations and companies in the European Union. These programs were carried out between 1979 and 1994. The EC has also produced recommendations (9) for recycling radioactively contaminated metals. These criteria are aimed mainly to minimize the radiological risks to potential users of the recycled material.

The OECD Nuclear Energy Agency's (NEA) Co-operative Program on Decommissioning set up, in 1992, a task group to study recycling and reuse of material from nuclear facilities. The Co-operative Program covers 30 decommissioning projects from 10 countries and thus represents the largest group of potential users of the criteria being drawn up in the area of recycling. Understandably, the NEA task group has treated recycling in a broader context than exclusively radiological aspects and

has studied it also from other viewpoints such as costs and the effects on the environment.

In the following is given a brief overview of the most relevant of the recycling projects sponsored by the European Commission as well as its recommendations for clearance criteria. The paper then goes on to describe some of the results of the work of the NEA task group and gives examples of case histories of recycling projects including cost comparisons with disposal as radioactive waste. The paper concludes with a brief outlook over future work being proposed in this area.

RECYCLING ACTIVITIES OF THE EUROPEAN COMMISSION

Recommendations for Clearance Criteria for Recycling of Metals (9)

Legal basis

The legal base for any action linked to radiation protection is the EURATOM Treaty set up in 1957. As far as radioactive material like metal scrap is concerned, the Treaty considers aspects of health protection, safety, and research and development. It gives priority to free access of goods to a common nuclear market and aims at establishing far-reaching Community competencies in a number of areas; the most important one concerning clearance levels for metals being the regulatory competence for setting up basic safety standards in radiation protection. These standards provide for common criteria which would have to be implemented in national legislation.

Technical and Scientific Background

Support for developing clearance levels was provided through the specific research and development programs on "Radioactive Waste Management and Disposal" and "Decommissioning of Nuclear Installations". Furthermore, in the "Plan of Action in the Field of Radioactive Waste Management", an instrument existed which allowed harmonization of practices and development of recommendations in semestrial meetings between Member States and the European Commission.

First contracts were concluded in 1983 with the UK National Radiological Protection Board and the French Commissariat l'Energie Atomique, to develop a methodology for evaluating radiological consequences of the management of very low-level waste, particularly solid waste from dismantling of nuclear power plants. The analysis of waste categories showed significant quantities of only slightly contaminated steel and concrete.

A range of activity values and scenarios for unrestricted release and decay times up to 100 years before disposal was assumed, and radiological consequences were found to be rather small. It was demonstrated that other factors than radiological consequences, such as costs for transport, treatment and measurements, and regulatory and social factors, for example acceptance by the public, may well be more important. The methodology developed in both contracts were later enlarged to recommendations on steel scrap recycling (9).

R & D work on release and recycling of contaminated steel and concrete has been an important part of the three five-year decommissioning programs carried out since 1979.From the results of these programs (1,3,4,5,6,7,8), input parameters could be derived, which were or will be used in scenarios calculations for proposing exemption and clearance levels.

Recommendations for Release Criteria

A Group of Experts had been set up under the terms of Article 31 of the Euratom Treaty, which convened a Working Party in 1984 to establish

radiological protection criteria for the recycling of materials from nuclear installations. The Experts prepared recommendations for criteria for recycling steel which were issued in 1988 (9). In the light of further information on recycling coming from later studies as well as due to revised radiation protection criteria, the Experts expanded and updated the 1988 recommendations to consider:

Criteria for other metals (steel alloys, aluminum and aluminum alloys, copper and copper alloys),

Criteria for surface contamination specific to recycling,

Covering all nuclear fuel cycle plants including installations for uranium enrichment, fuel production, power generation and reprocessing (but excluding mining or milling operations as well as final repositories).

A draft document has been prepared in 1994 suggesting nuclide specific clearance criteria for slightly radioactive materials of the types listed above. The radiation protection principles used by the Experts has been the 10 mSv per year individual and the 1 manSv per year collective dose per practice as recommended by the IAEA Safety Series No 89 (10). Separate values are given for equipment, components or tools which will be reused directly (only surface specific limits, Bq/cm2) and for material which will be recycled by melting (both surface specific, Bq/cm2, and mass specific, Bq/g). In the case of many nuclides, the surface specific clearance levels for material expected to be melted is a factor 10 higher than those for direct reuse.

Research and Development in the field of Recycling

Numerous studies, investigations, developments and technical demonstrations have been carried out mostly based on shared-cost contracts with a series of EU organizations and enterprises, such as for example TV Bayern, NRPB, KEMA, Siemens, Siempelkamp and CEA (1-8). The objectives of these activities have been waste volume reduction, more accurate activity measuring of the waste for further conditioning, free or restricted release. Melting of carbon and stainless steel components from nuclear installations for reuse is now state-of-the-art in Germany (Siempelkamp), where industrial conditioning of components originating from refurbishing or decommissioning of nuclear installations (e.g. KWO, KRB-A) is carried out in the authorized melt facility CARLA. Investigations at laboratory and pilot scale are being carried out with Siemens and Siempelkamp to investigate the decontamination effect of melting a- and H3-contaminated steel waste. Some of these projects are described below.

Melting of Ferritic Steel arising from the Dismantling of the G2/G3 Reactors, Marcoule (6)

The objectives were to condition by melting a large quantity of ferritic steel having a specific contamination in the order of 20-40 Bq/cm2 in a 15 t electric arc furnace and to determine the U-distribution in the molten product during a large-scale melt campaign of approx. 100 t (8 melts of 12.5 t each) of mild steel contaminated with uranium originating from the dismantling of the Pierrelatte reprocessing facility (Usines basse et moyenne). The amount of secondary waste arising was considered in particular.

Over 4300 tons of ferritic steel pipes were cast in 25 kg ingots, from which nearly 200 tons of total secondary waste were obtained. The ingots (25 kg) are stored on site, because the activity level for free release has not yet been decided in France.

Radioprotection measurements carried out by CEA's health physics specialists during the melts showed that no specific problems appeared, neither for the people working around, nor for the buildings. Detailed interpretation and results will be given in the final report to be published in the first half of 1996.

Melting of Tritium-containing Steel (8)

Important quantities of steel cannot be released from radiological surveillance because of their tritium contamination. The work consisted in trapping the tritium released from steel during heating and melting in a specially adapted exhaust system of the Siempelkamp CARLA melt facility.

During the melt process, the tritium passes into the exhaust gases where it was quantified in a bypass measuring section. Basically, it was demonstrated that steel contaminated with tritium can successfully be decontaminated. The predominant part of the tritium, more than 96%, is released as HTO or T2O in the course of the melt. The main release already occurs at temperatures below 500oC. The residual activity of the castings and the slag is negligible. To retain the tritium bonded to the air humidity, drying of the intake air is necessary.

Melting of Alpha-contaminated Steel (6)

The main objectives are to improve the decontamination effect by pre-oxidation process and the new slag former, as well as the radiochemical analyses of the behavior of Pu, Th and U-isotopes during melting, in particular the U-235 distribution in the molten ingot.

Laboratory melts aiming at the identification of the most suitable crucible material and slag former were followed by large-scale melts with subsequent detailed analysis of the prevailing alpha-distribution in and between steel, slag and filter dust (about 100 t of U and Th-contaminated material).

Decontamination factors of 44, 46 and 69 were obtained respectively.

Remelting existing steel ingots (+ 5 t) with subsequent radiological characterization was difficult due to the hardness of available ingots (no sampling possible). The use of uranium glass as an additive to the melt, to restore the natural isotopic ratio, gave good results (no dust and DF of 71/U, 192/Pu and 886/Th).

Using concrete as the new slag former gave no significant improvement.

Detailed interpretation and results will be given in a final report to be published during the first half of 1996.

Other Projects (6,7)

In addition to the above, there have been R & D projects carried out in the following areas:

- Recycling of aluminum and copper by melting,
- Doses due to the reuse or recycling of slightly radioactive steel,
- Industrial recycling and reuse in Germany,
- The onion melt technique for waste minimization and reuse of LLW steel in container fabrication,
- Volume reduction of contaminated/activated concrete,
- Concrete recycling in France,
- Radiological aspects of recycling concrete debris in Germany,
- Recycling of contaminated steel as reinforcement in concrete.

ACTIVITIES OF THE OECD/NEA TASK GROUP ON RECYCLING AND REUSE

The Task Group was set up by the Co-operative Program of the OECD Nuclear Energy Agency in 1992. The scope of the Co-operative Program is basically to exchange technical and other information between on-going

decommissioning projects. Since its start in 1985, it has grown to cover 30 projects from 10 countries, including a wide selection of reactors as well as fuel facilities. The Program has thus become the international forum for nuclear decommissioning projects. As such, it is deeply interested in all possible means of reducing the quantity of waste produced by such decommissioning. The recycling of such material, instead of disposing it as low level waste, was identified as a major method of achieving this aim.

The objectives of the Task Group were to:

make a survey over material currently being released from nuclear installations,

review the on-going work on proposals for clearance levels from the perspective of the potential users of such criteria,

make state-of-the-art surveys over the technologies necessary for recycling,

compare recycling/reuse of material with the alternative approach of disposal/replace from the viewpoints of

- total health risks (not just radiological risks)
- environmental impact
- socio-economic aspects
- costs.

During the three-year period covered by this paper, the work of the Task Group has been generally focused on metals. Its findings and conclusions to date are summarized in a report, currently being reviewed by the Nuclear Energy Agency's Radioactive Waste Management Committee and Committee for Radiation Protection and Public Health, prior to publication later this year. In the following is briefly summarized some of the findings of the Task Group.

Current Practice

One of the first activities of the Task Group was to map the current policies regarding the release of materials from nuclear facilities in various countries. Information was solicited from participating projects regarding the quantities and types of material released as well as the conditions governing their release. Information was received regarding 24 projects as well as the existing regulations in 6 countries. The projects included reactors, fuel facilities, uranium milling plants and isotope production facilities.

The survey revealed that over 360 000 t of material had been released between 1979 and the early 90's. The released material included carbon and stainless steels, lead, aluminum, concrete, soil and gravel. A variety of clearance alternatives had been adopted ranging from release for unrestricted reuse or disposal for about two-thirds of the material to restricted reuse within the nuclear industry. Most of the material was released after consideration on a case-by-case basis, even in countries where there are national regulations in place for the unrestricted release of material from nuclear facilities. An overview of the material released and the types of release practices is given in Table I (11).

Table I

A scrutiny of the released criteria used in the various projects and in the national regulations shows a wide range of values. For instance, Sweden has a beta-gamma surface contamination limit of 4 Bq/cm2 for unrestricted release, while in neighboring Finland, the corresponding limit is 0.4 Bq/cm2. The Finnish mass specific release limit is 1 Bq/g compared to the corresponding Swedish limit of 0.1 Bq/g. There are also

differences in measurement and documentation practices as well as in quality assurance requirements.

Health Risks/Environmental Impact

The International Atomic Energy Agency (IAEA) and the European Commission (EC) have both prepared recommendations for criteria for releasing material from regulatory control. Both proposals are based almost entirely on radiation protection and regulatory considerations.

The NEA Task Group represents projects which are the potential end users of such criteria. Understandably, the Task Group has studied clearance in a broader context, basing its approach on the recommendation of the International Commission on Radiological Protection (ICRP) regarding the justification for the adoption of a new practice involving exposure to radiation: "..... The radiation detriment may only be one of several aspects that comprise the total detriment associated with a particular practice. Consequently, the justification of a practice goes far beyond the scope of radiological protection.....".

The Task Group has therefore examined the justification for release of radioactive material by considering not only the risks from radiation, but also major non-radiological socio-economic, environmental and health effects. In this context, a "tiered" system of release criteria, with defined end uses for each tier, has been used as the basis for evaluating the various detriments and thus comparing recycling with the alternative approach of disposal of material as waste (12). The "tiered" approach is described in more detail in the section, "A Tiered Approach to Release Criteria".

Some of the results of these studies are summarized in the following Tables II and III.

Table II

Table III

Melting

The melting of contaminated metallic components has the advantages of

- a "decontamination" effect on volatile nuclides such as Cs 137 as well as on Uranium and other oxides,
- simplifying the radioactive characterization of components with complex geometries.

Four plants have been operating on an industrial scale during the last few years: the CARLA plant at Siempelkamp, Germany; the INFANTE plant at Marcoule, France; the SEG plant at Oak Ridge, USA; and the Studsvik Melting Facility in Sweden. At the decommissioning of the Capenhurst Diffusion Plant, U.K., a melting plant is being used to recycle large quantities of metals. A new plant is being constructed at Oak Ridge, USA.

Decontamination

For decontaminating equipment to recycling (release) levels, the methods used must have high decontamination efficiencies. At the same time, it must be possible to condition the secondary waste satisfactorily. Two methods satisfying these requirements have been demonstrated on a fairly large scale.

The Swedish SODP chemical decontamination method for PWR systems was used to decontaminate steam generators from the 80 MW gesta PHWR to near release levels. The steam generators were segmented and melted after decontamination.

A dry abrasive blasting method has been developed to recycle about 1 600 t of steel from the Eurochemic Reprocessing Facility. The method was first tested on a semi-industrial scale on a batch of 32 t.

Measurement

The currently proposed release levels are very close to background levels. This places very stringent requirements on the accuracy and reliability of the equipment and techniques used in the qualifying measurements for release. A large number of reports testify that it is possible to satisfy such requirements but most of the work in this area hitherto been on a laboratory scale. The practical problems of measuring very large quantities of material at extremely low activity levels and at a reasonable cost should not be underestimated.

The NEA Task Group has analyzed the case histories of 18 projects that used varying methods of recycling material from decommissioning projects. The projects are listed below in Table IV. The costs of some of these projects are compared with the respective estimated costs if the material in question had been sent for disposal as low level waste. The savings achieved by recycling are illustrated on Fig. 1.

Table IV

Fig. 1

A Tiered Approach to Release Criteria

As mentioned earlier, the evaluations of the Task Group are based on a "tiered" approach, with the highest tier (A) corresponding to unconditional release and each lower tier applicable to specific (conditional) release conditions. In the system used in the group's evaluations, the next highest tier (B) consists of material that is melted in a radiologically regulated plant and then is conditionally released for subsequent remelting and fabrication in non-nuclear commercial facilities. The products could then be used without radiological restrictions. The next tier (C) is material similar to that in tier B, except that the material is released for a specific initial industrial use. Material in the lowest tier (D) is recycled within the nuclear industry.

It should be noted that this is only one possible manner of applying the tier concept. One which would reflect the approach of the EC as well as practices in several countries is shown in Fig. 2.

Fig. 2

Here the tiers A and B correspond respectively to the EC criteria for direct release and for recycling by melting at a commercial foundry. The surface limits for recycling are more relaxed than those for direct reuse, because of the inherent advantages of melting. Tier C would cover waste metals melted at a controlled facility and then sent for remelting at a non-nuclear foundry. The release levels for the ingots leaving the controlled area could be expected to be higher than those for tier B, for equivalent levels of radiological safety. Tier D would consist of similar material as tier C but released for specified initial industrial use, while tier E material would be recycled within the regulated environment. In Fig. 2, tier C is similar to the management of contaminated metals at Studsvik in Sweden, while tier E reflects the activities at Siempelkamp, Marcoule and Oak Ridge.

OUTLOOK FOR THE FUTURE

As the technical problems of melting and recycling of low-level radioactive metal, if any, seem to be mostly at an industrial level, future activities in the EU may focus (besides some more specific R & D work, e.g. for alpha and tritium-contaminated materials, concrete recycling) on the development of common clearance levels and reliable standard procedures for their application, not only to contribute to the

establishment of harmonized regulatory requirements at Community level, but also with respect to future EU Member States and Eastern European countries which have vast quantities of radioactive material to deal with, such as the Chernobyl area. For this, co-operation between competent experts from the EU and the USA would be extremely useful. The NEA Task Group will continue in its efforts to place recycling in a perspective where it can be compared to other industrial activities. It will continue to work with other bodies to establish an international consensus concerning both the exemption and clearance of radioactive materials. In the development of regulatory criteria for recycling, the Task Group will work for a "global" optimization and not just optimization from a radiological viewpoint. This would lead to a more rational management of material in the nuclear industry.

ABSTRACT

Manufacturing Sciences Corporation, in partnership with British Nuclear Fuels, has designed and built what is recognized in the industry to be a state-of-the-art metals decontamination and melt facility. The partners have combined talents and experiences of their respective businesses to design and construct a facility that directly challenges the problems associated with existing approaches to metal recycle. This they achieved from concept to reality in less than 15 months.

This paper addresses the central design principles of minimizing worker exposure, industrial safety, Just-in-Time philosophy and process control. It will describe the comprehensive computerized traceability system, the extensive automated/remote handling, the main line decontamination processes, and the technologically advanced melt facility. Further, the approach to project/construction management will be discussed to demonstrate the value of extending the partners' ability as team players to include subcontract design and construction groups.

The purpose of this paper is to present a successful approach to the design and construction of a facility, with new and novel features, to meet an extremely aggressive schedule.

INTRODUCTION

Since the dawn of the nuclear age, maintenance and equipment replacement at power stations and other nuclear facilities have given rise to the need to dispose of contaminated scrap metals and equipment. These contaminated materials have been stored, buried, or decontaminated and released. Over time, responsible waste management become recognized as a significant cost of doing business in the nuclear industry. Beginning about 15 years ago, an industry emerged to provide low-level radioactive waste management services to the nuclear industry. Decontamination and release of those contaminated metals and equipment that could easily be cleaned and surveyed, and volume reduction and burial of those that couldn't, became a central offering of this embryonic industry. Early methods were manual, slow, and of low throughput. This decade has brought the end of the cold war and the prospect of decommissioning of U.S. Department of Energy (DOE) sites formerly used to produce nuclear materials and nuclear weapons. The DOE cleanup is expected to generate vast quantities of contaminated scrap metals requiring processing capacities far greater than those existing in the industry today. Recognizing that a safe, efficient and cost effective contaminated metals recycle capability to meet the expanded capacity and more stringent regulatory requirements of the future, two companies, Manufacturing Sciences Corporation and British Nuclear Fuels joined forces to design and build a modern contaminated metals recycle facility in Oak Ridge, Tennessee. This paper reviews the process of design and construction that resulted in a modern contaminated metals recycle facility.

DESIGN PHILOSOPHY

To address the issue of demonstrable capability through private sector investment on a scale which could address the potential needs of the customer, it was necessary to leap-frog existing technology used for recycle of radioactively contaminated scrap metal. Basic principles were established against which the facility design was developed:

- Zero emission objective
- Focus on industrial safety
- Just-in-Time philosophy
- Process control
- Recognition of local environment

To achieve a firm focus on the basic principles of minimizing worker exposure, high standards of worker safety and best practices in manufacturing, the fundamental obstacles of material handling and tracking had to be overcome. The varying form, type and configuration of materials to be handled drives processors away from automation and remote operation. The partners wrestled with this problem, finding this to be the major limiting factor on facility throughput. This issue required a paradigm shift to question how can the material be standardized. The solution identified was to transfer material in standard containers; 20 foot sea vans B25's, special design boxes and baskets etc. Handling systems for transferring material and processing material could then be designed around a standard container, components/material could then be tracked by virtue of the container in which it is housed. This shift in philosophy allowed the partners to adopt a number of special features for the facility which include:

- Automated undercover storage of incoming contaminated scrap metal.
- Remotely operated material handling.
- Semi-automated mechanical and chemical decontamination processes.
- Vacuum induction melting.
- Automated radiometric survey of material for free release.
- Fully computerized material tracking systems.

These features allowed development of a facility which in 115,000 square feet provides a full decontamination and melt capability for up to 10,000 tons of contaminated metals per year. The process is outlined in Fig. 1 and reflected in the facility layout in Fig. 2. Each stage of the process is discussed to highlight the significance of the change in philosophy to create an integrated facility.

Fig. 1

Fig. 2

PROCESS

Incoming Storage (Fig. 3)

Standardizing, where possible on 20 foot freight containers, allows automated storage and inventory control. Using a fully automated laser controlled crane for materials handling allows containers to be stacked two-high in a close packed storage array. Containers can be delivered to and released from the storage array without operator involvement, minimizing the associated operator dose uptake. This approach to storage, with a strict storage management regime, ensures containers with high activity levels can be shielded by containers with low activity levels, further reducing operator dose levels. This storage system allows the footprint of the storage area to be minimized allowing fully covered storage. On receipt containers are coded into the database of the Management Information System (MIS) using bar code scanners, and the manifest data is entered by the operator. All material movements from

this point and throughout the process, are electronically recorded to provide full on-line material tracking and control.

Material Preparation

The aim of standardizing processes is critical to achieving high volume optimized throughput but, to deal with the array of material and the differing types of customer projects, it has been necessary to implement two separate routes through to processing. The standard processing route involves tipping the contents from a container then remotely sorting and sectioning metals prior to decontamination. A special projects route allows for large component disassembly and sectioning for further processing and equipment decontamination and refurbishment prior to sale or return to the customer.

Unload, Sort and Section Area (Fig. 4)

This is an unmanned area which is used to routinely empty freight containers and to sort and section the discharged metals in preparation for later decontamination processing. The operator working in an enclosed control room operates a hydraulic lifting table and an industrial robot. The robot is used to distribute metals for sectioning to various saws and shears. Metals are tipped from the container and transferred using robust vibratory conveyors to the grit blasting equipment at the end of the process line or to the chemical processing area depending upon the desired method of cleaning. This approach reduces the workforce's exposure to contaminated materials and eliminates a primary source of industrial safety hazards.

All material leaving this area is loaded into standard material handling boxes and each box is weighed and coded into the MIS system using bar code scanning. This allows all material to be tracked back to the original freight container.

Special Projects Area (Fig. 5)

This area is dedicated to a variety of projects which are not suitable for processing in the automated area. These projects include dismantling of large components as well as refurbishing of a variety of valuable equipment. This area includes fully enclosed and locally ventilated painting, welding, grit blasting and sectioning. Relocatable enclosures and exhaust systems are used to allow reconfiguration of this area to accommodate the varying requirements of each task. Equipment that is broken down in this area for processing elsewhere is put in a standard material handling box, weighed and coded into the MIS using bar code scanning prior to transfer.

Material Handling

Materials are moved around the facility in boxes on two automated monorail systems. One monorail is dedicated to materials which have not been decontaminated, the other to materials which have been through the decontamination process. Each box loaded or removed from the monorail is bar code scanned to record the transfer in the MIS. The boxes used on the monorail have been specifically designed as a standard material handling box; these boxes are the only containers used to move material between processing areas. This approach to material handling significantly reduces operator involvement in material transfers, and minimizes the material stored in work areas, further reducing workforce dose uptake and exposure to industrial safety hazards. Additionally, it is a major step that introduces Just-in-Time production control techniques. Material is only delivered to an operator on request and material storage is limited

to that held on the monorail. This enforces a move away from the traditional problem of material stockpiles.

Mechanical Decontamination

The primary method of mechanical decontamination is grit blasting. The conveyors from the unload and sort area discharge directly into a fully enclosed batch process tumble blaster. This allows a process which has predominantly been carried out in manual grit blast booths to be carried out remotely, further reducing operator dose uptake. Additionally, using this approach, once experience is gained in material sizing, grit media and cycle times, process control techniques will be used to optimize the process and minimize wastes.

Chemical Decontamination (Fig. 6)

Material requiring chemical decontamination enters the area via the monorail system or the conveyor from the unload sort area. Material is loaded into baskets which are dipped in a series of chemical tanks and a spray washer via a monorail hoist system. The monorail system for this area and the chemical decontamination process are controlled automatically in a Programmable Logic Controller (plc). The operator bar code scans the basket and selects the appropriate chemical decontamination cycle for the material. On completion, the basket is transferred to a tipper station where the material is inspected and tipped into a box and bar code scanned prior to transfer to the survey area or foundry via the monorail system.

The tanks are provided with containments and extraction to remove fumes. The fumes are extracted through a scrubber system to the HEPA filters. The process equipment design ensures that the facility, with appropriate additions, can use any commercially available chemical decontamination processes. As with other areas previously discussed, the automated handling and operation further reduces workforce exposure and industrial safety hazards. The extent of automation, material flow control and process control provides an extremely efficient decontamination approach, allowing for process optimization and minimum waste.

Waste Handling (Fig. 7)

Wastes generated from processing operations are delivered to the area in boxes via the monorail system. Material is sorted into compactible and non-compactible wastes. Compactible wastes are processed via a shredder and drum compactor. Non-compactible wastes and wastes requiring stabilization are grouted in boxes. Drums and boxes filled in this area are dispatched to the special projects area for painting and labeling prior to shipping. As in all other areas using the MIS system, material delivered to this area can be traced back to the original container, allowing accurate allocation of wastes to each contract.

Foundry (Fig. 8)

Metals are delivered to this area in boxes by the monorail system. The contents of the boxes are segregated into batches for melting. All material used to make up a melt is recorded in the MIS to provide full traceability. Melting is carried out using a Vacuum Induction Degas and Pour (VIDP) furnace which produces high quality steel ingots. All scrap is cleaned prior to melting to ensure practically no slag is produced from the process. The furnace is fed on-line through a vacuum lock while melting is in progress. The VIDP is capable of refining steel by the introduction of reactive gases through a porous plug in the bottom of the melting crucible. A melt, once ready for casting, is delivered to the mold chamber via a separate vacuum chamber. Use of vacuum as opposed to

air melting ensures a high quality product, it minimizes slag production, and minimizes the potential for airborne contamination. All gasses produced during the melting process are extracted directly into the HEPA ventilation system, minimizing the reliance on room extraction to capture potential contaminants.

The main furnace operations are carried out by an operator in a remote control room. Various support operations are necessary for the melting process including mold preparation, which is carried out on a large fire brick lay-down area, crucible relining which is carried out in a separately ventilated room off the main foundry area, scrap metal sectioning for volume reduction prior to melting, and ingot preparation for future processing. As in other areas, reducing operator involvement with materials to a minimum reduces worker dose uptake and exposure to industrial hazards.

Laboratory

The laboratory services three main functions: radiochemistry, environmental analysis, and metallurgy. To support the QA program, the principles of Just-in-Time and the minimizing of in-process inventory, it has been necessary to provide a comprehensive range of instruments. It is necessary to provide this equipment on-site to obtain immediate results, thus avoiding the multi-day turnaround from outside services.

Survey for Release

Following each decontamination process, metals are dispositioned for melt or for survey prior to free release. The disposition decision is based on the level of remaining contamination, and the level of certainty with which the material can be successfully surveyed. Metals with residual contamination, or that which will not be surveyable, will be dispositioned for melt otherwise they will be dispositioned for free release. Metal ingots from the melt process can be used to fabricate products for restricted use.

Metals are received in the final survey area in boxes via the monorail system. The area contains semi-automated systems for counting and tracking 'removable' and 'fixed' contamination. Material is collected in scrap hoppers which are coded into the MIS system by bar code scanning. When results are available from the survey systems, the MIS system reports the status of the material for release. Once passed by QA, the material is moved to outside storage containers. Material that fails the survey will either be sent to the finishing area, where small areas of contamination will be removed, or it will be sent via the monorail to the foundry for melting.

DESIGN AND CONSTRUCTION MANAGEMENT

The design and construction of the RSMRP was carried out by a core project team of seven, with representatives from each of the main partners; two from BNFL in the UK, two from BNFL's USA subsidiary and three from MSC. This team was supplemented with various short term contract support as necessary. The project team extended the teaming approach adopted by BNFL and MSC to encompass the main contractors,including the Architect/Engineering Group, the general contractor, and major suppliers. In many instances, these external groups had representation at internal project meetings. In an environment of openness and clear objectives, rigorous project management and control techniques could be used in a positive and constructive manner. External groups were introduced to the project with a briefing on project philosophies. This briefing covered: budgets, schedule, contractor

relationship, styles of management, and most importantly, team concepts. Acceptance of these philosophies was a prerequisite to a group's involvement within the project. The result was a seamless relationship between the project team and the architect/engineers which fostered an open and critical design approach benefiting both parties. This approach was extended to the general contractor, their active involvement and the application of their experience, and resulted in a major value engineering exercise which reduced the facility's complexity and cost. The approach was initially treated with suspicion by major vendors, but as they began to experience the benefits of being allowed to do what they do best without the customer meddling, they became active members of the team. Clearly, the approach had varying degrees of success, but where it was successful, the results were dramatic, deliveries were on time, there were minimal contract claims, equipment actually conformed to requirements and partnerships were formed that will ensure the success of future projects.

The primary approach to scheduling was via simple milestones. Responsibility for meeting these milestones was delegated to those responsible for doing the work. The result was control systems ranging from detailed Primevera critical path networks, through Microsoft project schedules, to simple action lists. Using the appropriate tool for the task ensured support and ownership by the user. Backed by weekly project reviews, issues were constantly visible and corrective action was almost immediate. This process was backed by a detailed engineering and cost control system which ensured deviations due to errors, or changes in scope, were instantly highlighted. The approach allowed the team to complete the project within a $28M budget and on schedule:

- Site and vendor preparation October 1994
- Funding March 1995
- Site opening up April 1995
- First steel June 1995
- First receipt of active materials December 1995
- Operational March 1996

CONCLUSION

This project has demonstrated that the potential for future business can stimulate private investment in the creation of cost-effective and timely solutions for the customer. The imperative to find efficient solutions to the recycle issue has encouraged an innovative approach to break the barriers of existing metals recycle technology. This process has been strengthened and enhanced by a performance-oriented teamwork approach.

ELECTROLYTIC DECONTAMINATION OF STAINLESS STEEL MATERIALS IN A SODIUM NITRATE ELECTROLYTE FOR HAZARDOUS WASTE MANAGEMENT

Douglas E. Wedman
Horacio E. Martinez
Timothy O'Nelson
Los Alamos National Laboratory
Los Alamos, NM 87545

ABSTRACT

Electrolytic decontamination of plutonium and americium from stainless steel and uranium surfaces has been demonstrated. This decontamination process is similar to industrial electropolishing processes but is carried out in a sodium nitrate electrolyte from which the metals can be

precipitated. The separation of the metals from the electrolyte allows for recycle of the electrolyte; hence, no aqueous waste stream is produced. The generated waste is in the form of a precipitated and is therefore very minimal and compact.

An example application is a "can-out" process for the decontamination of radioactive material storage containers being developed at Los Alamos National Laboratory. This process utilizes electrolytic decontamination as its primary component. The "can-out" decontamination system and the underlying chemistry is outlined. Other successful applications of this technology are the in-situ decontamination of gloveboxes and highly enriched uranium.

INTRODUCTION

There are a variety of reasons for decontaminating surfaces, including lowering the radioactive waste categories of items, decontaminating items during processing to remove them from plutonium (Pu) gloveboxes, and enabling the disposition of special nuclear materials. In the past, many material surfaces were cleaned with concentrated acids that in turn produced large amounts of radioactive toxic waste. These acid wash methods are also inefficient for reducing contamination to desired levels.

Electrochemistry represents a viable alternative to these existing technologies for decontaminating a variety of radioactive and toxic wastes throughout the nuclear complex. Electrochemical methods produce significantly less waste and can also increase the efficiency of many existing processing technologies.

Electrolytic methods have been shown to be superior to acid washing methods. At the Los Alamos National Laboratory Plutonium Facility, we have been using electrolytic methods to clean a variety of conductive surfaces, including stainless steel and uranium. The focus of this paper is the application of this technology to a "can-out" procedure for the decontamination of nuclear material storage containers.

ELECTROLYTIC DECONTAMINATION

Electrolytic decontamination is similar to the common industrial practice of electropolishing and is accomplished by applying a low dc voltage through a suitable electrolyte to induce a chemical reaction at a mass-diffusion limited rate. Material is removed at the anodethe working electrodeand goes into solution. The cathode, or counter electrode, can be constructed from a variety of materials, but stainless steel is typically used. The electrolyte of choice for this process has been sodium nitrate at neutral to high pH because the radio active contaminants and major steel components form a precipitate. This precipitate formation leads to easy separation of the waste components from the solution; thus, the electrolyte solution can be recycled, greatly reducing waste as compared to past acid wash processes.

INDUSTRIAL ELECTROPOLISHING

Typical cold-rolled type 304L stainless steel has a microscopically rough surface as shown in Fig. 1. Allen and Randall (1) have documented many steel surfaces produced by various finishing techniques and have shown these surfaces to be disadvantageous when the material is introduced into a situation where surface contamination with radioactive species may occur. The disadvantage lies in decontamination difficulties related to the entrapment of contamination within these surface cracks and crevices. This is the case when dealing with containers that are designed for long-term storage of special nuclear materials. It is preferable to remove

this surface roughness before a possible contamination situation. Furthermore, mechanically polished materials are inadequate because of the many scratches and groove introduced by abrasives used in the polishing procedure. An electropolished surface, however, is microscopically smooth and creates no surface scratches that could entrap radioactive materials.

In industrial electropolishing methods, the material to be polished is submersed in an electrolyte bath and anodically polarized. With the passage of current, the surface layers of the metal oxidize to ionic species and then diffuse into solution. Under appropriate conditions, high points on the surface are preferentially removed resulting in a leveling of the surface. This polishing effect only occurs when the dissolution process is occurring at a mass-transfer limited rate. Typical conditions for electropolishing are well documented, based on the material to be polished (2). For stainless steel, the best electrolytes are composed predominantly of phosphoric and sulfuric acids in varying ratios. For a pretreatment of non-radioactively contaminated metal parts, these electrolytes are satisfactory. A typical electropolished 304L is shown in Fig. 2.

Fig. 1

Fig. 2

In the "can-out" process, the storage cans are electropolished by such an industrial technique prior to introduction to the glove box line. This prepolishing step assures that removal of only a few monolayers of the steel will be necessary to decontaminate the microscopically smooth surface of the can. As an example, a five-monolayer removal equates to only about 0.5 mgcm-2 of type 304 stainless steel.

ELECTROLYTIC DECONTAMINATION

Once a piece of steel has been surface contaminated with radioactive species, these industrial electropolishing electrolytes are not desirable. The high acid characteristic of these electrolytes would serve to dissolve oxides of Pu and Am and keep them in solution. After only a few articles are decontaminated, the material buildup within the electrolyte solution would mandate a changing of solutions and result in large quantities of radioactive toxic waste that must be treated and/or disposed. A better solution is to pick an electrolyte with a very low toxicity from which the radioactive materials can easily be separated; thus, the electrolyte can be recycled. Such a choice is a solution of sodium nitrate in water.

Passing an anodic current through a piece of stainless steel submersed in a sodium nitrate electrolyte results in dissolution of the steel. Childs and Winkel (3) have shown that this electrolytic removal of the surface layers of the steel can result in the removal of surface contamination. At the Los Alamos National Laboratory Plutonium Facility, we have demonstrated electrolytic decontamination of Pu and Am from stainless steel (4) and uranium (5) to contamination levels that enable materials to be removed from glovebox containment or that lower the radioactive waste category. For example, we have demonstrated the removal of alpha contaminants, like Pu and Am, from >1,000,000 counts per minutes (cpm) to approximately 1000 cpm by in situ electrolytic decontamination of gloveboxes (4). (The in situ method allows for the glovebox to remain installed to existing air handling.)

Removal of these contaminants lowers the waste category from a transuranic level to low level, greatly reducing disposal costs and

enhancing the likelihood of glovebox recycle. Although it is clear that the electrolytic decontamination process works, the chemistry of the process has not been fully characterized. In a previous paper (6), we reported that removal rates were found to be highest at higher electrolyte concentrations and in acidic pH. Satisfactory removal rates were found at sodium nitrate concentrations of 200 gL-1 and above. Stirring was also determined to be advantageous in producing a smooth surface. The appropriate current densities appear to be in the range of 0.1 and 0.2 Acm-2. Higher current densities result in higher metal removal rates, but adversely affect the surface morphology by causing roughening, pitting, or burning. These are all indicators of a non-uniform removal. At pH <2, metal removal rates are high and the resulting surface morphology superb, but precipitation of the removed metal and the actinides did not occur.

The dissolution reactions of the steel substrate in the electrolytic decontamination process are similar to those in electropolishing. Under mass-transfer limited current conditions in a concentrated sodium nitrate electrolyte, iron is oxidized to ferric ion and chromium to the hexavalent chromate ion. Nickel leaves the surface as nickelous ion. The other anode reaction is the oxidation of the solvent to evolve oxygen gas:

Eq. 1

Though the electrolyte solution may initially be at a neutral pH, the solution is quickly made alkaline due to the primary cathode reaction:

Eq. 2

Although hydrogen gas is produced as a byproduct of the electrolytic decontamination process, the rate of hydrogen production is so low that safety is not compromised, even in a glovebox environment (7).

Also, a small portion of cathodic current goes to the reduction of nitrate to ammonia:

Eq. 3

We have not yet quantified the significance of this reaction under the conditions of the decontamination process. Qualitatively, after running the system for extended periods of time, the faint oder of ammonia is detectable.

Under the alkaline conditions of the electrolyte solution, Fe3+ and Ni2+ have a very low solubility and precipitate as ferric and nickel hydroxides, respectively. Since the primary component in stainless steel is iron, the precipitate is largely composed of ferric hydroxide. This precipitate has a gelatinous nature and tends to incorporate other materials, including actinides, as it precipitates. In this respect, the electrolytic decontamination technique is similar to ferric flock procedures that are commonly used on an industrial scale to purify water.

CHROMATE REMOVAL

At the current densities of interest and at neutral to high pH, chromium is anodically stripped from steel as hexavalent chromium. In aqueous solution, hexavalent chromium exists in an acid-base equilibrium between the chromate and dichromate forms. At high pH, the predominant species is chromate, while at low pH, the predominating species is dichromate. Hexavalent chromium cannot be removed from aqueous solution as a hydroxide as are the other metals. This initial nonprecipitation is of concern because as the concentration of chromium rises in solution, it begins to adversely affect the electrolytic stripping process (3).

An electrochemical process for the reduction of hexavalent chromium and its subsequent precipitation has been demonstrated (8). Trivalent chromium, in contrast to hexavalent chromium, is readily removed from solution by precipitation as the hydroxide. Unfortunately, under the alkaline conditions of the decontamination process, the predominant form of hexavalent chromium is chromate. Chromate is difficult to reduce. Dichromate, on the other hand, is readily reduced either electrochemically or by addition of a suitable reducing agent such as the ferrous ion. Therefore, by acidifying the solution and carrying out a reduction, dichromate can be reduced to trivalent chromium. The trivalent chromium can subsequently be precipitated as a hydroxide by raising the solution pH.

THE "CAN-OUT" PROCESS

We are now in the stages of demonstrating a "can-out" process for radioactive materials packaging, which allows these materials to be packaged in stainless steel cans, the cans decontaminated, and removed from the contaminated glovebox line to the room environment. This process reduced Pu and Am contamination levels from the transuranic category to essentially "free release." The process utilizes the fixture in Fig. 3 for the electrolytic decontamination of the cans. This fixture is designed to suspend a welder storage can allowing electrolyte to be circulated through the gap between the interior of the fixture and the exterior can walls. The can is in electrical connection with the power supply by electrode contacts at the top and bottom of the can. The stainless steel housing of the fixture acts as the cathode during the decontamination step.

Fig. 3

The radioactive materials are placed within a previously electropolished stainless steel can and the can welded shut. The can is then placed inside the decontamination fixture from the "hot" side. A solution of sodium nitrate electrolyte is circulated through the fixture and the can polarized anodically to induce the dissolution of the outer layers of the stainless steel. As the material is stripped from the can, the iron, nickel, and actinides form precipitates within the electrolyte. These precipitates are then removed by filtration in either an in-line or batch mode. In an optimized configuration, the precipitates are filtered in-line, providing a clean electrolyte solution for recycle through the decontamination fixture. Due to the nature of the precipitate, in-line filtration is difficult, but we have had success with an appropriately scaled ultrafiltration module. Batch filtration is readily accomplished by allowing the precipitate to coagulate and settle after the decontamination step and prior to filtration. After decontamination, a water rinse is flushed through the fixture. The decontaminated can is then removed to the "cold" side of the fixture.

After a number of cans have been decontaminated, the chromate levels in the electrolyte must be reduced. To accomplish this, we are investigating an electrochemical reduction utilizing a sacrificial iron electrode (Fig. 4). The process involves first acidifying the solution to convert chromate to dichromate. The solution is then fed into an industrial electrochemical cell comprised of a stainless steel cathode and a sacrificial iron anode. As current is forced to flow through the cell, the iron electrode is oxidized to produce ferrous ion. In solution, ferrous ion undergoes a redox reaction with the dichromate to produce ferric ion and trivalent chromium. At the cathode, the primary reaction

is the reduction of water, though there is also some reduction of dichromate and some electrodeposition of iron metal.
Following reduction of the dichromate, the pH of the solution is raised by addition of sodium hydroxide. Both the trivalent chromium and the ferric ion precipitate as hydroxides and are subsequently filtered and removed from the solution. The electrolyte solution is then returned to the electrolytic decontamination process.
Fig. 4

CONCLUSIONS

The electrolytic decontamination technique has been shown to be a viable alternative to previous acid washing decontamination methods. It has overwhelming advantages in that the only waste generated is both minimal and compact. The electrolyte solution can be recycled indefinitely since all the contaminants are readily removed. Furthermore, unlike an acid washing process, electrolytic decontamination can be accomplished, no matter how much material removal is required, on a very short time scale. Material removal rate is proportional to the applied current, affording the operator control over the rate and degree of the decontamination. The "can-out" process for decontamination of stainless steel cans used in the storage of radioactive materials utilizes the electrolytic decontamination technique. Cold lab testing of the process has been very successful and a demonstration scale process will be installed in the Los Alamos National Laboratory Plutonium Facility for hot testing by the time of this conference.

THE NATIONAL CONVERSION PILOT PROJECT REGULATORY PROCESS

James G. Wambach

BNFL Inc.

ABSTRACT

Based on changes in the mission of the Rocky Flats Environmental Technology Site, and on a desire to accomplish tangible cleanup goals, the National Conversion Pilot Project (NCPP) worked in coordination with the regulators and the public to develop a more streamlined approach to decontaminating buildings at Rocky Flats. The result of this work is an approach remarkably like that described in the joint DOE/EPA Policy on Decommissioning Department of Energy Facilities under CERCLA, which was published almost 18 months after the NCPP began.

By emphasizing coordination and a common-sense approach to regulatory compliance, two unrelated efforts arrived at essentially the same conclusions.

INTRODUCTION

More than the name at Rocky Flats has changed. The site is now called Rocky Flats Environmental Technology Site; a name that reflects the myriad of changes at this site and across the DOE complex. With the end of the Cold War, the missions of the DOE and most of its sites have been replaced with missions that consider what to do with the buildings and people, while dealing with the by-products of previous missions. It has become clear that the DOE's primary goal now is to safely decontaminate the sites and facilities that are no longer needed for producing weapons. In addition to the new missions, most DOE sites are facing smaller budgets, members of Congress calling for the elimination of the Department, and levels of regulatory involvement that are higher than those faced in the past. To deal with all of these changes, and many more not mentioned here, the DOE realized that it needed a way to clean sites effectively, show tangible results, and meet the requirements of the regulators and the expectations of the public. In short, the DOE is looking to conduct business more like a private entity.

There are many efforts underway across the DOE complex that work toward this end; one of these efforts is the National Conversion Pilot Project (NCPP). Simply put, the NCPP is designed to recycle material, facilities, and workers. The project will employ former Rocky Flats workers to decontaminate metal-working facilities at the site to agreed upon levels, and then use the facilities and workers to recycle material that would otherwise be considered Low Level Waste into products that are useful to either the DOE or the private sector.

THE NCPP MISSION

The mission of the NCPP is "to explore and demonstrate, at the Rocky Flats Environmental Technology Site (RFETS), the feasibility of economic conversion at Department of Energy (DOE) facilities." Economic conversion is the conversion of facilities and equipment owned by the Federal government to production of goods by private firms for profit. However, not only buildings and equipment are being converted. Turning buildings on a DOE facility over to private use involves changing ideas about how things will be done, and about who will do them.

The NCPP was authorized in December 1993 by Secretary of Energy Hazel O'Leary to proceed in three distinct stages with a review and positive decision required at the end of each stage before proceeding to the next. The NCPP is being conducted through a Cooperative Agreement,which was signed April 1, 1994, between the U.S. DOE Rocky Flats Field Office (RFFO) and Manufacturing Sciences Corporation (MSC).

The NCPP has been divided into three stages, Stage I (feasibility and planning), Stage II (cleanup and refurbishment), and Stage III (recycling and manufacturing). There are decision points at the ends of Stages I and II and periodically during Stage III, to help ensure careful consideration of project feasibility and the opportunity for feedback from Stakeholders. At the end of each stage, the project could be revised or terminated, and DOE will only proceed with the support of regulatory agencies and the acceptance of the community.

To enhance the probability of a favorable decision at each of these points, and to ensure that tangible cleanup activities are achieved, the NCPP employed an approach that would:

- encourage public participation,
- establish an NCPP Steering Committee,
- build regulatory relationships,
- employ an Interim Measure / Interim Remedial Action as the regulatory vehicle, and
- transition away from DOE Orders.

Together, these activities create a climate that enables the NCPP to work with the interested parties (namely, the DOE, the regulators, and the public) to identify concerns and develop responses that are agreeable to all. The specific details of other projects will differ from those of the NCPP. However, the overall concept of identifying the affected parties, sincerely seeking their input, obtaining agreement on planned activities, and maintaining open lines of communication not only apply to other projects, it is vital to their success in light of the current situation. These five activities are discussed in the following sections.

PUBLIC PARTICIPATION

Public participation is one of the cornerstones of the NCPP, as evidenced by the requirement that public acceptance of the project be obtained prior to beginning each Stage of the project. The project's primary contractor, MSC, feels that informing and involving the public increases the likelihood of obtaining public acceptance. As demonstrated at many sites across the country (both DOE and commercial nuclear) the more the public knows about the activities on a site, the more likely they are to support those activities, to one degree or another. With the end of the Cold War, Americans demand to be more well informed, and are less likely to accept the reasoning that national security prevents them from having a say in activities that may affect them. By including members of the public in the planning process, many ideas that might otherwise not have been considered are identified and examined.

The NCPP public outreach program actually began before the project was initiated. Approximately six months before the NCPP was started, MSC began a campaign to inform interested stakeholders of the proposed project. The groups and individuals that MSC met with included representatives from cities and counties in the Rocky Flats vicinity, staff members from Colorado's congressional delegation, state representatives, local activist organizations, and community groups. In addition to providing information, the purpose of these meetings was to solicit comments and questions regarding the proposal.

The comments and questions received during this effort were researched and responded to in writing under the NCPP Issue Response Process. This process was administered by the NCPP Steering Committee, and is described in Section 3, NCPP Steering Committee.

The NCPP public outreach program continues, with periodic bulletins and pamphlets discussing the NCPP progress, and soliciting further public questions and participation. These are distributed to a list of over 500 individuals and organizations. In addition, the NCPP encourages visits and tours of the NCPP activities in progress. Tours of NCPP facilities have been provided to individuals and groups including the Secretary of Energy, personnel from other DOE sites, members of the international nuclear community, and other organizations at Rocky Flats and the vicinity.

NCPP STEERING COMMITTEE

Since the onset of the NCPP, a Steering Committee has been in place to help determine project-specific policy and respond to project-related issues. The NCPP Steering Committee is composed of members from each of the following organizations: MSC, DOE Rocky Flats Field Office (DOE-RFFO), the Environmental Protection Agency, Colorado Department of Public Health & Environment, Rocky Flats Local Impacts Initiative, the Rocky Flats Integrating Management Contractor, and the Colorado Office of Business Development. By involving these interested parties, including the regulators, in this process, regulatory issues can be dealt with more quickly and effectively. The NCPP Steering Committee, while having no regulatory authority, provides the project with a forum where regulatory issues can be discussed and guidance for the project developed.

As mentioned in Section 2, Public Participation, an Issue Resolution Process was developed that entailed the use of formal and informal methods to receive public comments. Comments were received through correspondence and public meetings. The Steering Committee maintained a log of all issues raised and tracked their status during the resolution process. The log did not attribute the issues to individuals in order to assure objective answers and maximize the chance of issues surfacing.

A number of subcommittees were developed to assist the Steering Committee. These subcommittees were composed of technical experts from the plant, the regulatory community, the Governor's Office and MSC. The Steering Committee then assigned each issue to the subcommittee that could most reasonably respond to the issue. Subcommittee subjects included human resources, site support services, environmental restoration, waste management, public outreach, and business planning. Once the subcommittee had researched the issue and developed a response acceptable to the subcommittee members, the response was forwarded to the Steering Committee. When the response was acceptable to all concerned, the responses were published and released to public reading rooms associated with the Rocky Flats site.

This process, while appearing complicated, provided the regulators, the public, and the NCPP with the opportunity to discuss issues in an open manner and to develop proposed resolutions without compromising official organizational positions. The Steering Committee continues to meet monthly to discuss progress on the NCPP and to provide guidance. The subcommittees will meet on an ad hoc basis during Stage II, as issues arise.

IM/IRA

Interim Measure/Interim Remedial Action (IM/IRA) Decision Documents are typically used as a vehicle for contaminant mitigation, abatement, and/or risk reduction under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) where there exists an imminent threat to the public or the environment. Although the NCPP poses no

imminent threat to the public or environment, the IM/IRA process was recommended by the Steering Committee, and is being used to establish and direct the achievement of a baseline for identified hazards that would allow the continued safe operations of the facilities by a private concern. Another reason for using the IM/IRA process is to solicit public involvement in the project.

The NCPP IM/IRA Decision Document identifies interim remedial actions for removal of uranium and chemical contaminants of concern, such as beryllium and others, which have been used within the three buildings that are associated with the NCPP. The remedial actions are proposed, not for reasons of mitigating an imminent threat, but rather, to evaluate cleanup techniques and to baseline the buildings, for the attainment of a safe and healthy workplace allowing future operations by a private concern.

REGULATORY RELATIONSHIPS

Over the course of the NCPP, emphasis has been placed on keeping the public and the regulators informed, and on obtaining and using input from these groups. Through the process of developing and refining the IM/IRA and its supporting documents, a unique relationship between the regulators and the NCPP has evolved. By including the regulators on the Steering Committee and holding numerous face-to-face meetings with the regulators on various subjects, what began as a somewhat distrustful relationship has become one of mutual respect where teamwork and professionalism are used to identify ways to accomplish common goals and comply with the applicable regulations.

As issues have arisen, the project continues to meet with the regulators to jointly develop proposed resolutions. By obtaining input from the regulators during the resolution planning, the NCPP benefits from the regulator's knowledge of the regulation as well as from their interpretation. This enables the NCPP to greatly reduce the possibility of misunderstandings with the regulators. It also provides the regulators with more timely information on the project, allowing them to better understand the issues facing the project.

The NCPP, each of the regulators, and various groups within DOE-RFFO have named one primary point of contact within their organizations. These individuals discuss any issues that arise, and obtain technical expertise from others in their organizations as needed to determine an agreeable resolution. This arrangement has proven to be a more streamlined approach than having each organization "working in a vacuum."

TRANSITION FROM DOE ORDERS

The intent of the project is for Stage III (recycling and manufacturing) to be performed entirely by a private company, under the regulations that any other private company would have to comply with. This goal will necessarily involve the elimination of the current requirement to comply with DOE Orders, since other companies in the open market do not have to comply with DOE Orders.

Since the NCPP buildings are on a DOE facility, they are currently subject to DOE Orders as well as regulations that apply to private business performing the same activities. There is some duplication between these sets of regulations that will need to be eliminated if the NCPP buildings are to be converted for use by a private business. Additionally, there are some DOE Orders that will not apply to a private business. The DOE requirements that are either duplicative or not applicable to private businesses will be identified by MSC, and

documentation will be developed that justifies eliminating the need for the NCPP to comply with the requirements.
At this point, the justification for eliminating the need for complying with the requirement will be presented to the DOE and the regulators. Once all parties agree that the justification is adequate, each will approve the justification.
CONCLUSIONS
An interesting side-note concerns the joint DOE/EPA Policy on Decommissioning Department of Energy Facilities under CERCLA. This policy, signed by both organizations on May 22, 1995 "is the result of a joint effort by EPA and DOE to develop an approach to decommissioning that ensures protection of worker and public health and the environment, that is consistent with CERCLA, that provides for stakeholder involvement, and that achieves risk reduction without unnecessary delay." This policy builds on the joint DOE/EPA goal to "develop decisions that appropriately address the reduction of risk to human health and the environment as expeditiously as the law allows."The NCPP was not related to the Headquarters-level efforts to develop the joint policy on decommissioning. But by focusing on the end goal of tangible cleanup achievements, and cooperating to find common ground, both efforts arrived at essentially the same conclusion.

Golden, Colorado 80402-4085

ABSTRACT
The National Conversion Pilot Project, currently underway at Rocky Flats Environmental Technology Site, Denver, Colorado, aims to show how ex-weapon production facilities within the Department of Energy (DOE) can become successful commercial operations. This project, unique within the DOE, is converting three major buildings on the plantsite in preparation for commercial metal forming/processing activities. Preparation for commercial operations involves the radiological and toxicological decontamination of the buildings, the removal of redundant facilities and the refurbishment of tooling and equipment required for operations. Project planning began in April 1994 with cleanup activities commencing in Building 883 in April 1995. Completion of cleanup work is expected during FY 1997.
Overall project management is the responsibility of Manufacturing Sciences Corporation (MSC) through a cooperative agreement with the DOE. BNFL Inc. is the principal subcontractor to MSC.
The NCPP can be viewed as a three way recycling project:
  The recycling of buildings and equipment from weapons production to commercial operation
  The recycling of scrap steel, as well as uranium and beryllium, away from weapon component production to commercial usage (e.g. the fabrication of waste storage boxes), and

The recycling of former Rocky Flats workers, made redundant following the plantsite mission change, from weapon component production workers to manufacturers of commercially viable products.

By recycling facilities, materials and labor, the project aims to show that the conversion of contaminated ex-weapons facilities into commercial uses can reduce the burden of underutilized facilities upon the DOE as well as being an economically viable commercial operation.

This paper describes the progress made to date in the decontamination and refurbishment of these facilities as part of the NCPP.

INTRODUCTION

The National Conversion Pilot Project (NCPP) is a recycling project currently underway at the Department of Energy (DOE) Rocky Flats Environmental Technology Site (RFETS) in Colorado. This paper describes the NCPP from inception through to the current status of the decontamination and dismantling work in progress on the plantsite.

HISTORY OF THE SITE

RFETS has an area of 6,500 acres and is located 16 miles NW of Denver, Colorado. The plantsite began operating in 1951, manufacturing weapons components and conducting plutonium processing operations. RFETS currently comprises numerous buildings within the plantsite boundaries with radiological or toxic contamination. In 1993, the production oriented plantsite mission changed to read "manage waste and materials, cleanup and convert RFETS to beneficial use in a manner that is safe, environmentally and socially responsible, physically secure and cost effective". This change of mission led to the cessation of production facilities with the plantsite entering a surveillance and maintenance state while cleanup plans and options were considered.

THE NATIONAL CONVERSION PILOT PROJECT

In 1993, Manufacturing Sciences Corporation (MSC) proposed to the Department of Energy (DOE) the radioactive and toxic cleanup of three major plantsite buildings in preparation for the possibility of using these refurbished buildings for commercial metal recycling and manufacturing operations.

The NCPP proposal involved three radiologically and toxicologically contaminated buildings on the RFETS plantsite (883, 865 and 444/7) with a combined floor area in excess of 200,000 ft2. Equipment within these buildings includes ovens, furnaces, presses, metal rolling equipment, shears, forges, lathes and other metallurgical processing equipment. Equipment of note includes nine vacuum induction melting furnaces, one new vacuum arc remelting furnace, two large rolling mills, a new 2000 ton extrusion press and six hydraulic forming presses including two 2000 ton presses and two 200 ton presses with 64" strokes This equipment would be valued at $92M if installed new today. Following the end of the Cold War and the change of mission at RFETS, these buildings and contents became surplus to requirements.

The buildings were selected principally because they contained machinery and tooling suitable for metal recycling operations. In addition, the buildings were located such that they could be accessed by contract personnel without affecting the security of other parts of the plantsite.

In April 1994, the DOE entered into a Co-operative Agreement with MSC to perform this work. MSC selected BNFL Inc. as its principal subcontractor to utilize experience gained by BNFL Inc.'s parent, British Nuclear Fuels plc, conducting similar cleanup at its UK sites.

AIMS OF THE NCPP

The NCPP mission is to "explore and demonstrate, at RFETS, the feasibility of economic conversion at DOE facilities". Within this mission, the NCPP has the following recycling intentions:

To re-employ former RFETS workers,

To reuse existing nuclear weapon component production facilities for the production of commercially marketable products, and

To reuse existing materials (uranium, beryllium and radioactively contaminated scrap metals) for the production of these products.

The NCPP was authorized in December 1993 by Secretary of Energy Hazel O'Leary with Stage I commencing in April 1994.

STAGES OF THE NCPP

The Project has three stages. Stage I was the feasibility and planning phase of the project and was completed in September 1994. Stage II is the cleanup and refurbishment phase during which unnecessary equipment will be removed from the facility, equipment to be retained for Stage III will be maintained and restored to operational use, and building contamination will be reduced to a level suitable for recycling operations. Stage III is the recycling and manufacturing phase of the Project when the reuse of facilities and materials will take place.

Stage I

The planning during Stage I for Stage II activities was guided by two principal considerations. These were whether or not equipment was considered useful for future Stage III operations (and if it could be economically cleaned and maintained within the Stage II funding) and the degree of contamination expected to be uncovered during dismantling. The decision on which equipment to keep was made by DOE. The remainder was categorized into the following groups in order of decreasing priority:

Equipment which could economically be decontaminated and moved to a separate DOE facility for reuse.

Equipment which could be economically decontaminated for unrestricted use outside RFETS and ownership transferred out of the DOE.

Equipment which could be economically decontaminated for unrestricted use outside RFETS and sold as scrap.

Unwanted equipment fabricated from metals suitable for reuse during Stage III which could be dismantled, decontaminated and stored pending Stage III recycling operations.

Unwanted equipment which could not be economically cleaned which will be disposed of as low level or low level mixed waste.

During Stage I, within the above guidelines, cleanup plans were established covering all three NCPP buildings. Characterization data were collected for each building which assisted cleanup planning and identified potential radiological and toxicological considerations. Stage I also involved marketing analyses, the production of training and staffing plans and regulatory oversight and site support service agreements. As well as cleanup during Stage II, it is proposed that operational assessment of equipment to be retained was to take place. Declassification of materials and tooling (approx. 272,000 lb.) and process verification for intended products will also occur in Stage II. In light of the proposed reuse or removal of items of equipment and the expected degree of contamination they may contain, a generic 10 step approach was devised which will be applied to each building in turn. Those ten steps are as follows:

Step 1 Removal of loose waste/unwanted equipment

Step 2 Cleaning of any high contamination hot spots

Step 3 Assembly of a centralized decontamination module
Step 4 Removal and decontamination of low contamination risk items of equipment
Step 5 Removal and decontamination of high contamination risk items of equipment
Step 6 Decontamination, dismantling and removal of utilities no longer required
Step 7 Repairs to building structure following equipment removal
Step 8 Dismantling, cleaning, maintenance, reassembly and testing of low contamination risk equipment to be retained
Step 9 Dismantling, cleaning, maintenance, reassembly and testing of high contamination risk equipment to be retained
Step 10 Final decontamination of complete building to operational levels
The above steps reflect the general principle of emptying the building of all unwanted equipment first, carrying out general repairs and then cleaning and refurbishing all remaining, wanted equipment.

Stage II

Stage II began in October 1994 and received regulatory sanction in April 1995 with the approval of the Interim Measures/Interim Remedial Action Decision Document which has been used to direct activities to take place in Stage II and to solicit public involvement in the project.
The Project is considered to be a recycling operation and, as such, recycling will be along three lines:

FACILITY RECYCLING

Each of the three buildings will be converted from weapons production operations to a part of a commercial metal recycling operation. Each building contains unique metal working equipment, much of it valuable, some of it unused but all still operable with, in some cases, minor maintenance. Unwanted equipment will be removed (as described above) for reuse elsewhere or, if not economically feasible to recover, either retained as recycle scrap for Stage III if suitable, or disposed of as waste. Equipment within the buildings will, as necessary, be reorganized. Wanted equipment will be refurbished after cleaning. Buildings will be returned to operational status prior to the end of Stage II.

MATERIALS RECYCLING

Each building contains materials which are suitable for recycling into commercially viable products. These materials fall into one of three categories: depleted uranium, beryllium and radioactive scrap metal. As each building undergoes cleanup, stocks of depleted uranium and beryllium, not required by the DOE, will be recovered and stored pending Stage III recycling. Radioactive scrap metal will arise from the cleanup process as unwanted equipment is dismantled and removed. Scrap suitable for use in future recycling operations will, after size reduction, be retained in the building. Not all metal scrap is suitable for recycling with stainless steel being the preferred Stage III feedstock. However, it is intended that substantial sections of other steels will be retained as additional feedstock materials. Within the three buildings, it is expected that 200,000 lb. of depleted uranium, 80,000 lb. of beryllium and 160,000 lb. of recyclable steel exist.

LABOR RECYCLING

With the change of mission, production operations ceased on plantsite with the result that labor would have to be shed. The final aspect of recycling concerns the reuse of labor made available due to the mission change. It is the intention of the project that the Stage II and III

workforce are made up from rehiring displaced RFETS workers. Many of the displaced workers have a working knowledge of the NCPP buildings, both operationally and through maintenance. Workers hoping to join the project will undergo a selection procedure which considers their existing skills and experience which are relevant to the project. Workers, when hired, will go through a cultural retraining and will receive training in essential areas where they do not have relevant experience. There is no 'blanket' training for all employees. Flexible working methods and a team approach to working practices are encouraged.

STAGE II CLEANUP METHODS

Stage II cleanup is being be achieved along the principle of local dismantling with a centralized decontamination facility within each of the three buildings. The choice of cleanup methods was determined on the basis of the known and expected contamination and radiation levels in each building at the time of planning. A predominantly hands-on approach was taken since:

- Contamination levels are not expected to be high enough to necessitate remote methods
- The project works to a fixed budget which precludes significant tooling investment
- The buildings are geographically split rendering a centralized, automated size reduction station impractical

In addition to the above considerations, the type of decontamination processes used was restricted by the type of effluent produced. Any liquid waste leaving the building will be processed through the RFETS effluent treatment facility which has stringent parameters for acceptance. Many of the effective decontamination solutions available on the market were incompatible with the effluent treatment system.

The cleanup systems chosen were wiping with acceptable decontamination reagents, vacuum cleaning, grinding, grit blasting and CO2 blasting. The CO2 system existed on plantsite though had been rarely used. The system was recovered, assembled and tested. It now operates in a HEPA-filtered booth as a non-destructive decontamination system which produces little secondary waste from its operation.

Dismantling methods are largely manual for many of the same reasons described in the previous section. For equipment to be dismantled, maintained and reassembled, hand disassembly (wrenches, etc.) are used however, for equipment to be disposed of, size reduction methods used include plasma arc and oxyacetylene cutting, cold cutting methods (saws, grinders, nibbler) as well as simple hand tools.

Wherever possible, decontamination is carried out centrally in the CO2 chamber with dismantling and reassembly operations performed locally.

CLEANUP PROGRESS SO FAR

Cleanup activities began, initially on a limited scale, in April 1995. The schedule for building cleanup is as follows:

- FY 1995: first half of 883
- FY 1996: second half of 883, 865 begins
- FY 1997: 865 completed, 444/7 cleaned

Delays in spring and summer 1995 prevented early commencement of cleanup operations in building 883 and, consequently, work on the first half of the building was completed, within budget, by the end of 1995. In anticipation of DOE funding for calendar year 1996, cleanup work has begun on the second half of the building.

At this time five decontamination teams exist and a number of decontamination and dismantling operations are in progress within Building 883. Within the first half of the building, all items to be disposed of have now been size reduced and either stored as recycle material or disposed of as waste. The items that have been dismantled and removed are the laser inspection table, nitric acid bath, sheet scrubber and small rolling mill. The equipment that will remain in the building half have been cleaned, dismantled, maintained and reassembled. These items include a large rolling mill (used for uranium sheet rolling), a 2000 ton hydraulic press, cooling water quench tanks, two shears and a radiant oven. Final work in the building half included floor repairs and building surveying and decontamination. In this half of the building, 91,600 ft2 of floor, wall and ceiling surfaces have been cleaned with 35,000 lb. of recyclable material retained for Stage III operations. In 1995, 903 ft3 of low level waste were transferred out of the building. During the same period, the amount of low level mixed waste created was 14.8 ft3.

Decontamination methods used so far have proved effective as much of the contamination encountered has been removable. Considerable success has been achieved using the CO2 system for removable material decontamination. Fixed contamination has been effectively removed using grit blasting methods where feasible.

Plasma arc cutting has proven effective and quick, particularly, in sectioning stainless steel. The use of containments with HEPA filtration has contained airborne contamination well though the smoke encountered using plasma cutters has shown a tendency to block filters prematurely if not used with effective prefilters. Other size reduction methods have been effective though more arduous than plasma cutting.

WASTES

Waste arising from all Stage II operations has been estimated at 53,500 ft3 of solid low level waste with another 20,000 ft3 of solid low level mixed waste. By comparison, the project is expected to generate over 335,000 ft3 of materials suitable for recycling in Stage III which would have otherwise been disposed of as waste.

STAGE III OF THE NCPP

Stage III is initially planned as having a five year duration with an option for extension if viable. Products to be manufactured in Stage III will utilize the facilities, materials and workers used during Stage II. Intended customers for these commercially viable products will be the DOE and other government and private interests.

It is intended that prototypes developed and fabricated during process verification activities in Stage II will become suitable products during Stage III. Typical products being investigated include coffee-tin sized stainless steel containers suitable for plutonium storage and 100 ft3 steel containers for LLW shipment and storage.

FUTURE COMMERCIALIZATION OF DOE FACILITIES

The aim of the NCPP is to provide a model of how weapons facilities can be converted into commercially viable operations. The success of the Project with the associated transition from DOE Order regulatory control to a NRC license will determine whether this type of operation can be attempted at other DOE facilities.

ACHIEVEMENTS OF THE NCPP SO FAR

Though only at the start of Stage II, the NCPP has achieved the following:

Reduction of risk by removal of radioactive and toxic contaminants
Decrease of operational, maintenance and security costs by removal of redundant equipment
Close co-operation with State and Federal regulators by involvement in project steering committee Demonstration of privatization of DOE facilities, equipment/building reuse by private industry
Hiring of dislocated RFETS workers
Obtaining public approval before commencing work
Aggressive public involvement program including community meetings, building tours
Sharing of results with other DOE sites

CONCLUSIONS

The NCPP is the first project of its kind to try and convert contaminated ex-weapons facilities into commercially viable operations. The cleanup and refurbishment operations in Stage II are a fundamental part of this project. The Project uses the experience of decontamination and dismantling operations from other facilities in the planning and execution of cleanup methods at Rocky Flats.

ABSTRACT

The concept of a consolidated effort to provide standardized waste containers for the DOE contractor network and the commercial nuclear industry has been discussed for some time. With the advent of the RECYCLE 2000 PROGRAM and the M-100 CONTAINER PROJECT, a serious effort is under way to develop a family of standard containers to be manufactured essentially from RSM, radioactive scrap metal.

The DOE's RECYCLE 2000 has as its mission: Produce 50% of the low level waste containers from RSM by the year 2000.

The headquarters initiative M-100 CONTAINER PROJECT has as its mission: Produce a family of containers to be manufactured from RSM that will satisfy 80% of the DOE's requirements. For the M-100 CONTAINER project to succeed, site consensus is essential.

This paper describes:

the M-100 family of containers
the methods used in gaining consensus from the contractor network
the determination of unique container requirements from each of the several disposal sites
the integration of such requirements into a universal design
the adaptation of unique closure and materials handling techniques

The integration of the RECYCLE 2000 PROGRAM, the BENEFICIAL REUSE PROGRAM, and the M-100 CONTAINER PROJECT will have a profound affect upon the availability of low cost, certified and documented containers as the DOE continues to clean its house over the next several decades. It is reasonable to assume that the commercial nuclear industry will judge the efficacy of the project and sign on as well. The eminent logic of constructing contaminated waste containers from contaminated steel cannot be denied. Ultimately, the cost benefit will accrue to the tax payer.

INTRODUCTION

The Department of Energy is exploring the task of converting its growing stores of radioactive metals into products useful to the nuclear community. The logical extension of such planning has been the development of a family of waste containers to be constructed essentially of radioactive scrap metal (RSM).

This paper presents three points which explicate the essential logic of the use of RSM for the construction of waste containers. The points at issue are:

1) RSM as a material for containers - the genesis of the concept
2) The development of the M-100 Container
3) The convergence of RSM, the M-100 Container and a dedicated manufacturing facility.

We believe that this paper will provide an understanding of this forward-thinking program and its benefit to the entire waste remediation effort.

RSM AS A MATERIAL FOR CONTAINERS - THE GENESIS OF THE CONCEPT

Congruent Needs and Concerns

The sites across the DOE network face essentially the same concerns in the remediation of waste. Each has waste products to be contained, scrap metal inventories and container needs. Logic dictates that an organized, common effort to deal with these concerns emerge.

The government owns countless tons of contaminated carbon and stainless steel material. These stores increase as the dismantling of site facilities continues. Demonstration projects are underway to determine the efficacy of returning such materials to a useful state in the form of sheet and plate. These projects will provide credible recycling and technology cost data which will be used as the basis for future judgments.

The waste remediation effort knows one essential waste container, the 4x4x6 "shoe box" shaped, carbon steel weldment. Millions of dollars are spent each year on such containers by all sites with waste packaging requirements. They are purchased from 30-50 different vendors...and they are all different.

However, the industry needs such containers. Each site enters into its own specification cycle, procurement cycle, testing cycle and ultimately, acquires sufficient containers to satisfy some remediation within some budget. The process has gone on for as long as the need was there...for decades. An alternative, innovative plan has been initiated by the DOE, its constituent elements known by many names: RSM, M-100, Recycle 2000, and Beneficial Reuse.

Compelling Logic

It makes economic and environmental sense to make products useful to the DOE network out of materials presently on site at DOE facilities.

It makes eminent sense to manufacture a standard family of containers that will meet the needs of all sites.

It makes economic sense to bring recycled materials to a dedicated facility to be fabricated into containers for use by the DOE contractors. The logic of rendering useful the increasing liability of contaminated scrap metal through recycling and its beneficial reuse cannot be denied. Contaminated scrap has no intrinsic value. Through the effective disposal techniques of recycling, radioactive scrap metal can be returned to its ultimate value and beneficial reuse.

The use of RSM as a container material carries with it familiar control practices well known to the industry and implies a facility licensed and dedicated to contaminated production.

It therefore follows that efficient use should be made of such facilities. A container family, designed to be produced in quantity, and a facility tooled to accommodate such containers defines synergism.

It is possible to create a basic container design which may satisfy the requirements of 7A TYPE A as well as STRONG TIGHT with such uniform and consistent features one to the other so as to greatly enhance manufacturing economies and permit just-in-time inventories. Such is the container to be produced by a dedicated RSM facility. The M-100 short list of containers of standard design and certification can be used by all sites to satisfy their needs.

The progression from recycled metal to standard design to dedicated facility assures consistent quality, uniform design and certified, low-cost containers.

From the short list catalog, each site may satisfy the large fraction of container needs. It is understood that site bias and on-going established programs will result in reticent attitudes toward a new program.

Change comes with difficulty but change also comes with information and education.

The goal shall be to make the container design the "standard of the industry." Such an effort may require a missionary zeal but the eminent logic, the beneficial costs, and container availability will probably win.

Recycle 2000 Program

RSM (radioactive scrap metal) may be defined as, "Those metals in inventory at the several DOE sites, classed as low-level waste which may be candidates for recycling."

The program "Recycle 2000" instituted by the Department of Energy has as its goal producing 50% of the DOE's low-level waste container needs from RSM by the year 2000.

In support of this goal a number of demonstration contracts have been awarded to define recycling techniques and demonstrate their efficacy.

The M-100 Development Program

The Department of Energy as a companion program to Recycle 2000 has issued a small development contract to provide waste boxes to be made essentially from RSM. The M-100 project has as its mission: to produce a family of containers to be manufactured from RSM that will satisfy 80% of the DOE's needs.

A unique container family has been designed, constructed and tested. All have identical external dimensions. All are designed for maximum storage efficiency. The container envelope contains a nominal internal volume of 90 cubic feet. Such volume permits a pay load of compacted soil equivalent to 9,000 lb.

In an effort to gain more universal usage, we have altered the familiar box geometry to permit the containment of a six-pack of standard 55

gallon drums. While the aspect ratio varies somewhat from the conventional box, we believe the added use benefit to be an important consideration.

The scope of work requires a container design in STRONG TIGHT and 7A in both 12 ga. and 7 ga. carbon steel sheet. The logic here is to establish a design that will permit those who are only able to produce heavier materials to participate in the M-100 program.

We approached the task on a worst-case basis, selecting 12 ga. material and a 7A test protocol. By building and testing a prototype in this configuration, we are assured that the heavier 7 ga. container will pass the 7A tests as well.

The 7A prototype (Model M-101/7A/12/90) is constructed with a system of internal struts so that it can sustain the vertical load as required by the NTS Waste Acceptance Criteria (120,000 lb. approx.) and the 7A drop test as required by the Code of Federal Regulations. (See Fig. 1)

Fig. 1

If we remove some of the struts from the prototype, the container is reduced to a STRONG TIGHT design capable of sustaining the NTS vertical load requirement but not the 7A drop test. (Model M-101/ST/12/90) (See Fig. 2)

Fig. 2

At least two of the major sites do not require the NTS static load capacity. By removing additional struts from Model 101/ST/12/90, we reduce the container to a system that will sustain a vertical load equal to five (5) times its gross weight (35,000 lb. approx.). Again the 7A drop test is not required. (See Fig. 3)

Fig. 3

This reverse progression, designing initially to the 7A standard, permits the development of a container family, essentially identical in external appearance, applying lesser standards where appropriate, while protecting manufacturing efficiency and economy.

Four (4) container models have been established as the M-100 series.

Table I

Gasket

The design technique of using a flexible gasket requires a pull down of the gasket sufficient to prevent a leak path. Care must be taken to prevent extreme compression such that the gasket cells are crushed causing the material to loose its resilience (compression set). We reason that such over compression must be prevented to protect the gasket material's flexibility.

The normal array for filled storage containers is to stack one upon the other. Individual site requirements vary from a stacking load of five (5) high at SRS (about 35,000 lb.) to the NTS overburden requirement of 120,000 (approx.). Such loading sustained by the lower most container may severely crush the cells of the gasket if the container design does not protect it. If one unstacks the containers for retrieval, the crushed gasket has been rendered ineffective and no longer provides an environmental barrier.

The M-100 container is constructed such that the vertical stacking load is taken through the cover and the cover bolts and transferred to the box wall. The gasket sees no severe compression no matter what the storage conditions may be.

Fasteners

Among the criteria used in selecting a closure system must be:

- ease and convenience of use
- a requirement for no special tools
- in process opening and closing
- temporary and permanent closures
- absence of proprietary design infringement
- cost

Bolting is the simplest, most universally accepted method for mechanically fastening one or more parts. Simple is best. The Rivnut/Bolted Closure has precedent in container designs presently in use at the DOE sites. Rivnuts (or their equivalent) are used standardly by WIPP in the Standard Waste Box. K-25 has a patented box which uses a series of 38-bolts and Fernald uses a bolted flange for its 6-drum box. To close the container and compress the gasket, one must do the following:

- beginning at the corners, insert a drift pin through the cover hole and into the threaded Rivnut
- skip a hole and repeat the process
- place a bolt in the skipped hole
- repeat at all corners
- fill in the gaps

For temporary or in process closure, one need place only three or four bolts on a side.

The M-100 container series is designed with an off-set at the upper perimeter. Such a system affords the fasteners protection during test and random shipping events. In addition, the off-set provides space for a unique apparatus which can lift the container cover alone or, with the cover in place, the container and its payload. (See Fig. 4)

Fig. 4

Aside from top fastening containers such as the K-25 7A box, most closures require some space beyond the container wall to accommodate the closure fittings. The M-100 design permits absolute side by side, zero clearance, storage between boxes. The lifting apparatus which permits hoisting from the top of the container obviates the need for fork lift risers.

Risers

A compelling case can be made for inexpensive, removable or disposable fork-lift risers. Conventional, permanent risers permit a void space on the order of 4-5 cu. ft. per stored container. A container without risers can be stacked one upon the other with no clearance. For the present, the disposal sites require permanently affixed risers. Such risers are part of the M-100 designs. We postulate, however, that the industry will ultimately accept the concept of removable or disposable risers as its standard.

Burying Money

The divergent approach to container requirements among the several sites is curious. We have seen a proliferation of container designs with less than desirable storage efficiencies - that ratio of inside volume to outside cubic measure. Little attention has been given to void spaces created by closure appurtenances and risers. Literally all of these void spaces can be eliminated through innovative design. A properly designed container may reduce void space in the repository by 10-12 ft3 per stored container. Translating this to dollars at $45.00 per ft2 equals $540.00 in void space - a sum which will more than pay for the container.

The predominant use of fork lifts as the principle transporter of waste containers has necessarily placed limitations upon external container design. This fact together with an industry unwillingness to accept removable, recyclable or disposable risers causes the storage inefficiency to be preserved.

An absolutely smooth-sided, cubic container with neither appurtenances nor fork lift risers fitted with a top-lift hoisting arrangement will minimize the money buried with each container.

An indicator of storage efficiency is the ratio of internal to external volume.

M-101/7A/12/90 efficiency 93%
M-101/ST/12/90 efficiency 95%
M-101/ST/12/90/A 97%
M-101/ST/7/90 97%

The Task Force

To assist with the container definition and to maximize the contribution of ideas and concerns from the sites, a task force of twenty eight (28) people was assembled representing all of the major sites and many of the DOE offices. No funding existed for travel and site visits. With few exceptions, all communication with the task force and the DOE took place via fax or phone. Over time and with the influence of the task force, a single design emerged which has the probability of meeting the container needs of all the sites.

The task force contributions in many ways became a study in conflict resolution.

LMES Oak Ridge required a boxed riser
Fermco insisted upon a wide flange beam riser
None would agree to a removable or disposable riser
NTS ultimately decided to consider removable risers in the next revision to the waste acceptance criteria (WAC)

LMES strongly suggested that any cover lifting device must be capable of lifting the container and its contents. This extremely challenging requirement permitted a vast improvement in storage efficiency, allowing containers to be stored one upon the other without fork lift risers.

Yet to be resolved is the material thickness issue. Ten gauge steel is the requirement of at least one (1) major site. The M-100 container is constructed of 12 ga. or 7 ga.

SRS has an absolute geometry requirement for its low-level waste containers. Other sites do not. The M-100 container continues to be at odds with the SRS standard.

Three (3) members of the task force represent SRS. Two (2) are in active agreement with the M-100 effort, yet SRS has released a five year blanket order agreement (BOA) with no consideration of the M-100 effort.

Much of the waste will ultimately reside at NTS stored in STRONG TIGHT containers. Such containers require a 120,000 lb stacking load

A large fraction of the waste will be stored at SRS and LMES in STRONG TIGHT containers. Such containers require 35,000 lb stacking load.

The disconnects and the discontinuities continue. Such divergent requirements were aired through the M-100 container task force teleconferences. While the M-100 container will not be "all things to all people," we believe it to be sufficiently well considered to become the industry's standard and satisfy 80% of the container requirements.

The DOE, for its own reasons, selected a small firm to execute the M-100 task. Its support and direction have been motivating. It is, however, the

contributions from the task force members at the sites that has given the design its credibility. While the significant task (primary job) of gaining consensus remains, the task force approach with its early contribution assures a high probability of such agreement.

THE CONVERGENCE OF RSM, M-100 AND A DEDICATED FACILITY

The Next Step

The M-100 container designs have been constructed and tested and await that first opportunity for a limited "real world" production run. That opportunity may come in the form of an arrangement between Fermco and Oak Ridge wherein RSM will be shipped to LMES but returned to Fernald in the form of finished containers to the M-100 design. This opportunity will provide valuable information regarding fabrication techniques and manufacturing cost data.

If a new product is to be introduced to the market place, the essential step after constructing engineering prototypes must be value analysis; that process of evaluation which permits cost reduction without compromising the design. As the Fernald requirement evolves, such an analysis should be conducted.

The Pitfalls

The Department of Energy initiated the Recycle 2000 and the M-100 programs and has effectively managed them through the early rocks and shoals. Demonstration containers have been made from RSM. Recycling facilities are underway and the first production order is in the offing. Such is the early progress of which success is born.

To every up side there is a down side, however. The down side or pitfall in this project's road is apathy, indifference, inertia and that attitude institutionalized at many sites which says, "We have our own program. Our containers are different. This is the way we have always done it."

With the advent of RSM as a useful and available material for container fabrication and the acceptance of the M-100 design, it is reasonable to consider a fabrication facility dedicated to the task of producing containers for the waste remediation effort. Logistical considerations would suggest two facilities: one in the east, probably mid-south and one in the west. Such facilities will be planned and tooled to provide just-in-time shipment of M-100 containers from stores of inventoried containers. Since the shell components of the M-100 containers are identical (walls, struts, covers, etc.) sub-assemblies can be fabricated well in advance. The M-100 logic provides for the multiple use of components and a "building block" approach to container fabrication. Properly equipped and strategically located, such facilities can produce the ultimate container value.

CONCLUSION

We have addressed the issues of radioactive scrap metal (RSM) as a container material, described in detail the emerging M-100 container program and introduced the convergence of RSM, M-100 and the dedicated facility.

While a serious effort has been made to include the sites through task force involvement, an early and on-going effort is needed to gain acceptance to the point of implementation of the M-100/RSM containers. The compelling logic of the Recycle 2000/M-100/dedicated facility movement requires re-thinking the conventional procurement cycle, design and test cycle, and contractor/vendor interaction. It requires a paradigm shift - a new model, a new way of thinking, a collaborative effort which shall assure the most efficient use of the government's stores of

radioactive scrap metal to produce M-100 containers of high quality and the greatest value to the tax payer.

ABSTRACT
The Los Alamos National Laboratory (the Laboratory) Pollution Prevention Program Office sponsored a Value Engineering (VE) workshop to evaluate recycling options and other pollution prevention and waste minimization (PP/Wmin) practices to incorporate into the decommissioning of the Omega West Reactor (OWR) at the Laboratory. The VE process is an organized, systematic approach for evaluating a process or design to identify cost saving opportunities, or in this application, waste reduction opportunities. This VE workshop was a facilitated process that included Department of Energy representatives and a team of specialists in pertinent areas, including of decontamination, decommissioning, PP/WMin, cost estimating, construction, waste management, recycling. The uniqueness of this VE workshop was that it used an interdisciplinary approach to focus on PP/WMin practices that could be included in the OWR Decommissioning Project plans and the specifications to provide waste reduction.
The OWR Decommissioning Project is currently in the planning and preliminary assessment phases. Preliminary waste projections were estimated, and the Laboratory's Solid Radioactive Waste Management Group established a maximum volume of waste from the OWR that will be accepted for disposal. The decommissioning of a nuclear facility, such as the OWR, is expected to generate very large quantities of waste, including low-level radioactive waste (LLW), low-level mixed waste (LLMW), and hazardous waste (HW). Many of these waste materials (e.g., concrete, steel, wood, soil) may have a potential for recovery, recycle, and reuse. Because the high cost of waste management and the limited capacities for treatment, storage, and disposal of HW, LLW, and LLMW, all practical efforts must be used to reduce the volume of generated waste.
The VE team evaluated the Preliminary Decommissioning Project plans and recommended specific PP/WMin work practices that can be incorporated into the final Project plans, operations, and contract specifications to reduce the volume of generated waste and increase material recovery opportunities. The VE team considered decontamination, source reduction, recycling, and volume reduction techniques and technologies that are currently available at the Laboratory, within the Department of Energy, and in the commercial private sector. Emerging technologies or research

and development technologies were not considered. VE workshop results included the following:

- Over 13 recommendations and action items identified
- Specific PP/WMin practices that can be immediately incorporated to result in an estimated waste volume reduction of 2,399 m3 of LLW, sanitary waste, and Toxic Substance Control Act waste and save approximately $1.17 million in waste management costs
- Potential PP/WMin practices that could reduce an additional 1,251 m3 of LLW

INTRODUCTION

The Pollution Prevention Program Office (P3O) at the Los Alamos National Laboratory (the Laboratory) pilot tested an effort to integrate individuals with pollution prevention and waste minimization (PP/WMin) expertise into environmental restoration (ER) and decommissioning programs. The objective of the integration was to demonstrate that PP/WMin techniques can be (and have been) applied to the Laboratory's ER and decommissioning activities to minimize the volume of waste that requires subsequent treatment, storage, or disposal and to reduce waste management costs. In addition, the effort identified potential tools and systematic approaches for reducing wastes from ER and decommissioning activities.

As part of this effort, a Waste Minimization Value Engineering Workshop was conducted to focus on reducing wastes and recycling materials from the planned decommissioning of the Laboratory's Omega West Reactor (OWR). The Value Engineering (VE) workshop was sponsored by the Laboratory's P3O and the Department of Energy (DOE) Office of Environmental Management, in cooperation with the Laboratory's Environmental Restoration Program, Decommissioning Project. Benchmark Environmental Corporation planned and participated as team leader in the workshop; and the workshop was lead by an independent, certified VE facilitator.

The VE workshop evaluated the preliminary project plans for the OWR Decommissioning Project and recommended over 13 specific PP/WMin work practices that can be incorporated into the project plans and specifications to reduce the volume of generated waste. This paper presents the results of the Waste Minimization Value Engineering Workshop and discusses the use of VE as a tool to minimize the waste generated from future DOE decommissioning projects.

BACKGROUND

The Laboratory's Environmental Restoration Program assesses and cleans up sites and facilities that have been contaminated from past DOE activities, including the safe decontamination and decommissioning of inactive nuclear facilities. ER activities, in general, and decommissioning activities in particular, have the potential to result in large quantities of low-level radioactive waste (LLW), low-level mixed waste (LLMW), and hazardous waste (HW). There is a challenge to reduce (or avoid) waste that will require subsequent treatment, storage, and disposal for several reasons, including limited on-site and off-site capacities for waste treatment, storage, and disposal and the high cost of radioactive and hazardous waste management.

In 1995, the P3O began integrating with the Laboratory's Decommissioning Project Office (DPO) to incorporate waste reduction practices, where appropriate, and to evaluate existing tools or systematic approaches for incorporating PP/WMin as a standard practice in future projects. Jointly, the P3O and the DPO identified VE as a potentially effective tool for

decommissioning projects to identify and incorporate PP/WMin practices. The OWR Decommissioning Project was selected as a test case for the VE process.

The OWR Decommissioning Project was selected because it was in the planning and preliminary assessment stages and the project was expected to generate large quantities of waste, including radioactively contaminated soil, equipment, building debris, concrete, scrap metal, and personal protective equipment (PPE). It was then proposed to conduct a VE workshop on the OWR Decommissioning Project that would focus on recycling and waste minimization practices that could be incorporated into the project plans and specifications.

VE WORKSHOP OBJECTIVES

VE is an organized, systematic approach for evaluating a process or design to identify cost saving opportunities. The process uses functional analysis to challenge the designers, engineers, and project planners to consider alternative approaches that provide the same function. VE has traditionally been applied to engineering design projects in the conceptual, Title I, and Title II phases, and it has provided significant return-on-investment (ROI) of the costs spent to conduct the study and implement the VE recommendations.

The VE team included decommissioning representatives, PP/WMin representatives, cost estimators, construction specialists, decontamination specialists, waste management, recycling specialists, and other appropriate technical personnel.

The primary objective of the VE workshop was to identify and recommend specific work practices (e.g.,segregation) and PP/WMin practices that could be incorporated into the Decommissioning Project plans and operations to reduce the volume of generated waste and increase material recovery opportunities. The specific objectives included the following:

- Identify and prioritize specific decommissioning activities that are expected to generate waste
- Identify recycling opportunities and work practices that will reduce waste or increase material recycling
- Identify available technology or services needed to implement the PP/WMin practice
- Develop draft language for specifications or procedures to guide implementation of the waste minimization or waste reduction ideas
- Develop preliminary cost estimates for the practices with the highest potential and evaluate, by ROI or other cost analysis, which are the most feasible
- Recommend PP/WMin practices that the OWR Decommissioning Project should implement

The workshop focused on minimization, decontamination, and recycling concrete, steel, metals, and soil, which are expected to be the highest waste volumes. The VE team considered recycling, decontamination, and volume reduction techniques and technologies that are currently available at the Laboratory, within the DOE, or in the commercial private sector. Emerging technologies or research and development technologies were not considered.

Preliminary documents reviewed by the VE team included the Preliminary Project Plan (1), the Preliminary Characterization Report (2), and the Preliminary Waste Management Plan (3). Preliminary waste projections were estimated and the Laboratory's Solid Radioactive Waste Management group established a maximum volume of waste that will be accepted from the OWR.

Waste acceptance may be contingent on the expansion of the current on-site disposal area.

OWR DECOMMISSIONING PROJECT SUMMARY

The OWR Facility was originally constructed in 1943 and housed five nuclear reactors between 1943 and 1995. The first nuclear reactor was a low-power, water-boiler reactor and was the first reactor in which enriched uranium-235 was used as fuel to achieve a self-sustaining nuclear reaction. After several conversions, the final water-boiler reactor was completely shutdown in 1974 and dismantled in 1989. A 25 kW, fast-neutron research reactor, which used plutonium fuel surrounded by mercury coolant, was constructed on-site and brought to full power in 1949. This reactor was dismantled in 1954, after discovery of a fuel element failure leading to plutonium contamination of the mercury coolant (1, 4).

The final reactor, the OWR, was built on top of one of the previous water boiler reactor foundations and is still present. The OWR is a tank-type reactor, which has a full power rating of 8 megawatts (MW) thermal. The reactor is light-water moderated and cooled, and uses aluminum clad, MTR-type fuel elements. A coolant leak in an underground pipe was identified in 1992 and the OWR was shut down. That pipe and another pipe have since been removed. The remaining pipe stubs connected to the reactor are welded shut or capped. The OWR has not operated since discovery of the leak (1).

In 1994 the fuel and all control blades were removed from the OWR, and the OWR was placed in a safe shutdown mode. The reactor vessel has been drained of all coolant. During defueling operations, the fuel elements were inspected and no damage had occurred.

Decommissioning activities will address the ancillary buildings, facilities, and equipment; remove the reactor vessel and biological shielding; and survey, decontaminate, and demolish the main building. Decommissioning activities will include asbestos abatement; detailed radiation surveys; decommissioning of contaminated components and separation of radioactive and nonradioactive materials; detailed radiation survey for material or equipment release; demolition or disposal of material or equipment; and backfill to grade. After decommissioning activities are complete, the site will be turned over for Resource Conservation and Recovery Act facility investigation and corrective measure activities (1).

A preliminary characterization was performed in early 1995. The OWR characterization is consistent with the operation of a nuclear reactor that used enriched uranium as a fuel. Activation products, radioactive contamination, and primary coolant isotopes include cobalt-60, nickel-59, nickel-63, strontium-90, and cesium-137. Radiological contamination includes high levels of radioactivity internally located at the fuel element grid plate and nearby ports in the reactor tank (i.e., 2600 R/hr, primarily activated cobalt-60 in experimental ports). Contaminated areas include the following: reactor tank tops; building roof; concrete-capped floor; painted areas (fixed contamination); ion exchange resin, pumps, filters, and piping; primary surge tank; three underground storage tanks; cooling tower heat exchanger air handling blower and exhaust stack; and building walls and floors (less than 5000 dpm/100 cm2). Contamination inside the primary system, lead shielding, and foundation concrete is unknown (2).

Projected waste generation from the Preliminary Decommissioning Project plans is shown in Table I. No recycling or waste minimization requirements were identified for the project specifications; however, the following, ten, very general, PP/WMin practices were identified in the preliminary plans (3):

Conduct routine briefings
Segregate wastes to avoid mixing and cross-contamination
Remove contamination and reuse equipment and supplies
Remove visible and radioactive contamination from disposable items before discarding
Avoid the use of organic solvents during decontamination
Use drip, spray, squirt bottles or tanks for decontamination rinses
Use impermeable materials such as plastic liners or mats and drip pallets to prevent the spread of contamination
Practice contamination avoidance
Reduce waste volume
Consider waste treatment and recycling operations

Table I

VE WORKSHOP ACTIVITIES AND RESULTS

The steps for planning and conducting the VE workshop are shown in Fig. 1. The VE workshop was conducted over three days and followed a typical VE job plan as outlined in Fig. 1.

Fig. 1

The VE team developed over 13 recommendations that have a high potential for waste reduction and should be included in the Decommissioning Project plans. The recommendations are discussed below.

Seven recommendations can be immediately implemented that will reduce waste generation by an estimated 2,399 m3 (778 m3 of LLW, 1,621 m3 of sanitary waste, and 0.4 m3 of Toxic Substance Control Act (TSCA) waste), with an estimated project savings of $1.17 million in avoided waste management costs.

Two recommendations for radioactively contaminated concrete could potentially avoid 501 to 1,251 m3 of LLW concrete (saving $0.79 to $1.98 million in waste management costs). These recommendations were considered to be technically feasible and have very high potential for LLW reduction; however, they required longer implementation and negotiation efforts to resolve potential regulatory acceptance barriers.

Four recommendations are applicable to reduce or avoid LLW, but are nonquantifiable from a waste avoided and cost savings perspective.

- Dedicate one person with authority to make waste management, minimization, and recycling decisions and to provide technology direction or assistance, as necessary.
- Build incentives into the contract for reaching specific source reduction, volume reduction, and recycling goals (i.e., contractor keeps proceeds from recycle; media-specific incentives and goals are established; bonuses for project managers are provided; and waste management dollars are given to project up front).
- Change Laboratory and DOE rules so that consistent interpretation of rules is possible throughout projects. For example, allow free release of waste below limits; allow wasteform averaging; allow the use of explosives; set realistic waste acceptance standards for disposal.
- Include specific requirements in project specifications in requests for proposal. For example, require project-specific waste minimization and salvage plans; disallow disposal of specific recyclables; require

volume reduction before waste packaging; specify how waste will be characterized to meet criteria for disposal.

The nine quantifiable recommendations are identified in Table II. Cost savings include only project- related waste disposal costs; the entire cost to the DOE complex was not quantified.

Table II

The VE workshop findings and recommendations were presented to Laboratory program managers (i.e.,ER, decommissioning, waste management) and DOE representatives. There were no major objections to the recommendations. Admittedly, some might be difficult to implement, but none were identified as entirely unreasonable or impracticable. One raised issue was that this workshop did not identify any new techniques, but only identified practices that currently existed at different locations and for different on-site projects. The VE team acknowledged that fact, but felt that the information might not have been as quickly and effectively shared with the OWR Decommissioning Project personnel if left to chance and not gained through a formal process like VE. Without such an organized formal approach, the pressure of a project schedule, other work load pressures, and personal agendas often combine to inhibit such sharing and application development.

CONCLUSIONS

On the basis of the results from the VE workshop and the management briefing, it was concluded that VE is an effective tool for incorporating PP/WMin into decommissioning projects. Further, the VE workshop was beneficial to the participants and to the OWR Decommissioning Project. However, improvements can be made to the VE workshop process. The process appears to be most effective for large projects (e.g., high waste generation, high cost).

As a PP/WMin tool, the VE process was effective in developing specific ideas for reducing waste, including LLW and sanitary waste, and reducing (or avoiding) waste management costs. In addition, the process increased awareness of PP/WMin requirements and practices, and it enhanced communication between the Laboratory's decommissioning project and the P3O because it provided an opportunity for the interested parties to influence practices that are integral to their day-to-day responsibilities.

Over 70 percent of the VE team reported that the workshop was valuable, and they would recommend using the process again on a larger-scale with respect to waste generation and cost. Over 60 percent believed waste would actually be reduced as a result of the workshop's recommendations, if implemented; the other participants believed it was too early to predict the actual benefits. The cost savings identified during the VE workshop far exceed the cost of planning and conducting the workshop; and the cost for implementing the VE recommendations is expected to provide a high ROI in terms of avoided waste management cost to the OWR Decommissioning Project.

Lessons learned from the workshop are summarized below and should be considered in the planning of future VE studies.

- The process can be streamlined to shorten the length of the workshop
- The process can be combined with existing project technical review milestones or project planning and design meetings
- Project management commitment is needed to ensure followup to the recommendations developed during the workshop

Active participation by all interested parties must be encouraged (or enforced)

More advance notice should be given to participants, and complete background data should be provided before the VE workshop

In conclusion, VE can and should be used for large waste volume decommissioning projects as a tool to ensure that the decommissioning activities are planned and evaluated with an eye toward PP/WMin and that decisions made with respect to PP/WMin are documented.

POLLUTION PREVENTION AND WASTE MINIMIZATION AT THE WATERVLIET ARSENAL THREE SPECIFIC EXAMPLES

William C. Goldberg
Michael G. Lewis
MSE Technology Applications, Inc.
Butte, Montana

Phil Darcy
Watervliet Arsenal
Watervliet, New York

ABSTRACT

MSE Technology Applications, Inc., (MSE) is a Department of Energy (DOE) contractor and operates the Western Environmental Technology Office (WETO) for DOE'S Office of Scientific Development (OSD).

In this capacity, MSE not only evaluates innovative technologies for application in environmental restoration and pollution prevention but also actively promotes the transfer of these technologies to a broad spectrum of users.

The Watervliet Arsenal, located outside Albany, New York, in the city of Watervliet, is a site where several technologies developed in the private and public sectors are being implemented to prevent pollution and reduce waste generation.

A description of the technologies will be provided with a discussion of the approach used to select and implement the appropriate technology. Technologies that will be discussed include: state-of-the-art Coolant Management Systems used to clean and recycle coolants used in large-scale machining operations, application of anaerobic bacteria to reduce toxicity of chromium-contaminated waters, and utilization of a systems approach combining technologies from two vendors to treat chromium-contaminated water.

In addition to brief examinations of the three specific technologies, the approaches used to bring together several diverse participants to form an effective team and implement technology transfer will be outlined. This work is being performed under the DOE Contract number DE-AC22-88ID12735

and is funded by the Department of Defense (DOD) under the supervision of the U.S. Army Corps of Engineers, Construction Engineering Research Laboratory (USA/CERL) with the cooperation and support of the Watervliet Arsenal.

INTRODUCTION

Background

In May 1994, MSE Technology Applications, Inc. met with U.S. Army Corps of Engineers' Construction Engineering Research Laboratory (CERL) representatives to discuss potential projects for industrial wastestream remediation and minimization at the Watervliet Arsenal in Watervliet, New York.

Ten separate pollution control or waste minimization projects have been initiated as a result. In the following paper a summary of three of the technology demonstrations currently in progress will be presented. These technologies are focused on two of the Arsenal's major waste streams: 1) contaminated machine tool coolants; and 2) chromium contaminated water form hard chrome plating operations.

PROJECTS

Machine Tool Coolant Recycle.

Oil based coolants used to cool machine tools frequently become contaminated with grease and dirt from the components being machined, and also with oils that may leak from the machine tools themselves. Additionally, the quality of the coolant can be degraded by replenishing evaporative losses with hard water resulting in poor quality coolant emulsion. The approach to solving this problem in one major manufacturing area that utilizes a 40,000 liter coolant sump to supply a number of large machine tools was to provide reverse osmosis water for coolant preparation and replenishment, and install a system to remove tramp oils from the coolant.

Chrome Plating Rinse Water Recycle

Gun tubes manufactured at the Watervliet Arsenal are chrome plated in large 12 meter deep tanks. Following the plating process the tubes are rinsed in tanks of fresh process water. When the chrome level in the rinse water exceeds approximately 100 mg/l, the concentration is lowered by dilution with the effluent (tank overflow) being sent tot the onsite industrial waste treatment plant for chrome removal prior to discharge. The pilot scale demonstration evaluated a system comprised of two vendors' technologies for recovery of hexavalent chrome from the rinse water. The system consisted of electrochemical extraction of hexavalent chromium, effluent particulate microfiltration and reverse osmosis final polishing.

Treatment of Chromium Wastestreams using Sulfate-Reducing Bacteria

The use of sulfate-reducing bacteria to mitigate hexavalent chromium-contaminated waste water at the Arsenal is also being evaluated. A bench-scale bioreactor system is being operated and results evaluated at the Department of Energy Western Environmental Technology Office (WETO) in Butte, Montana.

TECHNOLOGY EVALUATIONS

Machine Tool Coolant Recycle

Coolant in the large (40,000 liter) sump at the Arsenal's Flexible Manufacturing area typically becomes contaminated with tramp oils and bacteria. This coolant must be replaced at least annually or at times more frequently, and the contaminated coolant must be shipped offsite for disposal as a special waste. By supplying demineralized make up water and

providing a system for removing tramp oils and bacteria, an indefinite coolant life is anticipated.

A reverse osmosis unit was installed in the facility to supply demineralized make up water and a new batch of coolant has recently been prepared using 20 parts water to 1 part mineral oil. The demonstration is continuing to evaluate both the coolant quality and the effectiveness of the tramp oil and bacteria removal system.

Selection of a coolant recycle system was accomplished by developing performance specifications and soliciting proposals from a number of vendors. Proposals were evaluated on the basis of cost and effectiveness resulting in selection of a Sanborn Pioneer Coolant Recycle System.

The Sanborn Pioneer System was installed in the Flexible Manufacturing area of the Arsenal, and a four-week proof-of-process test was initiated on September 15, 1995. During the course of this test, coolant samples were collected and analyzed to evaluate the systems effectiveness in reducing the bacteria count and removing tramp oils from the coolant. Bacteria count was typically reduced from 5.0 X 107 colony forming units/ milliliter (cfu/ml) to less than 10 X 103 cfu/ml by the pasteurization process. The bacteria count in the sump was reduced to a minimum of 9.5 X 104 cfu/ml, but typically remained in a range of 2 X 105 to 4 X 106 cfu/ml.

Initial tramp oil content in the coolant was 4 to 5 percent by volume. After 2 weeks of operations, the tramp oil content was reduced to 0.5 percent. As Fig. 2 illustrates, the tramp oil content then oscillated as a series of major hydraulic leaks on machine tools leaked large volumes of oil into the sump.

Chrome Plating Rinse Water Recycle

The demonstration to treat chromium contaminated rinse water took place at the 120mm Chrome Plating Facility on the Watervliet Arsenal, Watervliet, New York.

The demonstration evaluated the effectiveness and cost of hexavalent chromium recovery and rinse water effluent treatment compared to current Watervliet Arsenal methods of handling chrome rinse water.

The two vendors involved with the demonstration were the Memtek Division of Wheelabrator and their Retec Chrome Recovery System and ZENON Environmental Incorporated and their Microfiltration/Reverse Osmosis Treatment System. The two technologies were connected in series to a 2800 gallon chrome rinse tank for hexavalent chromium recovery, filtration, and final polishing. (Fig. 2) The Eltech Retec chrome recovery system demonstrated electrochemical extraction of hexavalent chromium from the rinse water. The ZENON Microfiltration (MF) and Reverse Osmosis (RO) units demonstrated effluent particulate microfiltration and final polishing respectively.

Seven sample streams were analyzed during the demonstration. The seven sample streams were:

1) RTE (Rinse Tank Effluent): Process water prior to any treatment processes;

2) CO (Catholyte Outlet): Rinse Tank Effluent after electrochemical treatment in the Retec Cell;

3) Anolyte Outlet: Electrolyte solution for the Retec Cell. Anolyte Outlet is recirculated through the Retec Cell and acts as a heat sink and reservoir for the recovered chromium;

4) MFP (Microfiltration Permeate): Catholyte Outlet after microfiltration treatment;

5) MFC (Microfiltration Concentrate): Stream containing solids from Catholyte Outlet Stream;
6) ROP (Reverse Osmosis Permeate): Polished process water after reverse osmosis treatment; and
7) ROC (Reverse Osmosis Concentrate): Reject Reverse Osmosis process water.

These streams were sampled, when applicable, on a daily basis and analyzed for Cr, Fe, and Pb. Iron and lead were below instrument detection limits on virtually all samples. Bent Laboratories on the Watervliet Arsenal performed all analytical work associated with this project.

The three technologies were installed as an end-of-pipe (2) treatment "system". Since the treatment technologies represent two separate companies, each treatment was evaluated individually wherever possible. The effectiveness and maintainability of each unit was evaluated on an individual basis. The economic viability of each technology was evaluated separately and as a part of the entire "system".

The Retec Cell was successful at removing chromium from the rinse water when the power source, rectifier, was supplying a high DC amperage to the cell and/or the flow through the cell was low (0.5 - 1 gallons per minute). Single pass recovery rates of approximately 70-99% were observed under these conditions. However, these recovery rates could not be maintained for more than a few days. Cleaning the unit, a 1.5 hour procedure, brought single pass recovery rates back up to desirable levels. The Retec Cell was simple to use and easy to maintain. Total operational costs for one year are estimated at $7,500.

The ZENON Microfiltration Unit could not be evaluated for particulate microfiltration effectiveness due to delays in receiving analytical results. The microfiltration unit was easy to operate and maintain and total operational costs for the microfiltration unit for one year are estimated at $4,800.

The ZENON Reverse Osmosis Unit was successful at final polishing of the rinse tank effluent. Percent rejection rates of 99% and an overall decrease in the conductivity as illustrated by Fig. 3 of the 2800 gallon rinse tank were observed as a result of using this unit. Total operational costs for one year for the Reverse Osmosis unit are estimated at $65,000. Ninety three percent of the total operational costs of the unit are associated with cooling water (4.5 gpm) required for operation.

TREATMENT OF CHROMIUM-CONTAINING WASTESTREAMS USING SULFATE-REDUCING BACTERIA

MSE is performing laboratory-scale experiments to determine the effectiveness of using Sulfate-Reducing Bacteria (SRB) to reduce Cr(VI) concentrations in industrial wastewater. This project is being conducted as part of a group of projects being performed at MSE called the Department of Defense Construction Engineering Research Laboratory Projects (Industrial Waste Stream Pollution Prevention Projects) which address concerns at the Watervliet Arsenal (WVA) in Albany, New York.

The acid wastestream produced at the WVA contains a significant concentration of Cr(VI) (29 mg/L on average). Largely because Cr(VI) is a carcinogenic substance, it is desirable to reduce the Cr(VI) to Cr(III), a much less toxic substance. Presently, WVA is reducing Cr(VI) to Cr(III)

in the wastewater by adding sulfuric acid and other reagents to promote the following chemical reaction:

$2CrO_4^{2-} + 3SO_2 + 2H_2SO_4 \rightarrow Cr(III) + 5SO_4^{2-} + 2H_2O$

The Cr(III) is subsequently precipitated as a hydroxide: however, sulfuric acid is an expensive, dangerous reagent.

Through the laboratory experiments, MSE is evaluating the use of SRB to treat chromium-containing wastewaters. SRB are naturally occurring, heterotrophic, anaerobic bacteria, which are found in nearly all natural environments on earth. Sulfate-reducing bacteria decompose simple organic compounds using sulfate as a terminal electron acceptor, thus producing hydrogen sulfide, H_2S. The testing is being performed within several batch bioreactors in a laboratory at the WETO facility located in Butte, Montana. The bacteria are cultured and injected into bioreactors containing Cr(VI)-containing wastewater and are nourished with a low-cost organic substrate. The H_2S needed for the reduction of Cr(VI) is produced by the SRB. The use of biogenically produced H_2S is safer and more cost effective than the traditional H_2S or sulfuric acid sources. Cr(VI) is reduced through the following chemical reaction:

$3HS^- + 6FeSO_4 + 4CrO_4^{2-} + 13H_2O + OH^- \rightarrow 3S + 6Fe(OH)_3 + 4Cr(OH)_3 + 6SO_4^{2-}$

The primary objective of the laboratory-scale testing is to determine if SRB are effective in reducing Cr(VI) concentrations in synthetic solutions (initial concentrations varying from 25 to 55 ppm) and in WVA waste streams (initial concentration approximately 25 ppm). The tests will also determine if SRB, once established, can withstand a sudden increase in Cr(VI) concentration (an intervention event).

Secondary objectives of this project are to evaluate the treatment system for technology effectiveness and cost effectiveness. This information will allow the project personnel to assess the applicability of the technology for treatment of the WVA wastewater at field scale and the manner in which the technology should be applied.

Preliminary experimental results indicate that SRB are capable of reducing Cr(VI) to Cr(III). Figure 4 presents Cr(VI) concentrations over time in a reactor with an initial Cr(VI) concentration of 25 ppm.

Fig. 4

CONCLUSIONS

Machine Tool Coolant Recycle

Initial test results indicate that machine tool coolant life can be extended to at least several years or more, in contrast to the past practice of annual or more frequent change out. This results in an annual savings of approximately $21,000 comprised of disposal costs ($10,000), coolant purchase ($5,000), and labor ($6,000). There are additional less tangible benefits including: 1) reduced odor which creates a better work environment; 2) reduced incidence of dermatitis among machine operators, 3) reduced machine maintenance, 4) increased cutter tool life, and 5) improved product quality. Although several years of documented operating experience will be required to fully validate the above benefits, all results to date strongly suggest significant cost, quality, and environmental benefits will be realized through installation and use of the coolant recycle system.

Chrome Plating and Rinse Water Recycle

The treatment system for recovering chrome and cleaning the chrome-plating rinse water wastestream was not cost effective. Although the Retec Cell was effective in removing chrome from the rinse water, there was not sufficient chromium available for recovery to offset the

electrical costs. The cell would be best utilized to treat a wastestream with significantly higher chromium concentrations than those in the final rinse tank. (<75ppm)
The microfiltration reverse osmosis units were employed to clean the chrome rinse water for either recycle to the final rinse tank or for discharge. However, the energy consumption by the two units exceeded the benefits derived from reduced make up water requirements and reduced waste water treatment costs at the existing on-site industrial waste treatment plant. This situation prevails even if the RO cooling water is recycled to the plant process water system.
Installation and operation of treatment systems that do not reduce costs relative to existing systems, is not justified under current conditions. In the event a plant were required to operate as a zero-discharge-facility (regardless of the cost), then use of microfiltration and reverse osmosis to clean process water for recycle could be justified.
Treatment of Chromium-contaminated Wastestreams Using Sulfate-Reducing Bacteria
At the time of this publication, testing and evaluation of SRB effectiveness is still at the laboratory scale, and a cost-benefit analysis has not been performed.

U.S. Department of Energy
Savannah River Site
ABSTRACT
The U.S. Department of Energy has established a pilot team to implement pollution prevention activities at the Savannah River Site. Over the past year, this pilot team has worked to build a strong foundation for the site-wide pollution prevention program. This program covers over a thousand waste stream at more than one hundred facilities. The four primary building blocks used by the pilot team for initiating its program include: 1) developing a site-wide pollution prevention policy and manual; 2) establishing a site-wide pollution prevention council; 3) successfully integrating pollution prevention criteria into contracting mechanisms; and 4) developing a technical assessment guide. While these four building blocks represent a strong foundation, the pilot team has much work left to do while it constructs the site-wide pollution prevention program.
INTRODUCTION
The Savannah River Site (SRS) was established in 1950 by the U.S. Atomic Energy Commission (subsequently, the U.S. Department of Energy) to produce isotopes for national defense and peace-time applications. Many of the wastes that were generated as a by-product of performing its mission are now stored at a variety of facilities at SRS. Current activities at SRS include storing and treating high-level liquid radioactive waste, managing low-level radioactive solid waste,

investigating and remediating radioactive, hazardous and mixed-waste sites, producing radioactive isotopes for NASA, and maintaining nuclear weapons. These activities provide an on-going source for the generation of both radioactive and non-radioactive waste streams.

SAVANNAH RIVER SITE PILOT POLLUTION PREVENTION PILOT TEAM

Although waste minimization programs have been used at SRS for several years, the U.S. Department of Energy (DOE) has recently developed a comprehensive pollution prevention (P2) program for SRS. Over the past year, DOE has taken the responsibility for developing and implementing a P2 pilot program and creating a team of DOE personnel to manage this pilot program. The DOE P2 pilot team defines pollution prevention as the use of materials, processes, and practices that reduce or eliminate the generation and release of pollutants, contaminants, hazardous substances, and wastes into land, water, and air. P2 at SRS includes practices that reduce the use of hazardous materials, energy, water, and other resources along with practices that protect natural resources through conservation or more efficient use. The P2 pilot team is working toward establishing a comprehensive P2 program by implementing cost-effective P2 and waste minimization strategies.

One of the primary responsibilities for the P2 pilot team is addressing cross-cutting issues that affect all contractors working at SRS. This responsibility will become even more critical as SRS awards its next Management and Operations (M&O) contract as a multi-contractor award, which means that several contractors will be performing many of the tasks currently being performed by a single contractor. In addition, privatization efforts are continuing at SRS, thus allowing other DOE contractors to work at SRS outside of the existing M&O contract. The P2 pilot team is given the unenviable task of managing the SRS P2 program for all current and future contractors at SRS. The team members, however, are in the best position to coordinate and manage such a program. The structure of the P2 pilot team is presented in Fig. 1.

Building a Solid Foundation

The P2 pilot team's first task was building the framework for a site-wide P2 program. This framework is the foundation for the site's P2 program. The P2 pilot team recognized that a comprehensive P2 program should be strong enough to handle over a thousand waste streams from more than one hundred facilities, yet it also needs to be flexible enough for mission changes as well as changes in its primary operational contract. The following are four primary building blocks that the P2 pilot team used for initiating the SRS P2 program:

- Developing a P2 Policy and Manual
- Establishing a P2 Council
- Successfully Integrating P2 Criteria Into Contracting Mechanisms
- Developing a Technical Assessment Guide

Each of these building blocks will be discussed in the following four sections.

Developing a Pollution Prevention Policy and Manual

A key aspect of any successful P2 program is a commitment from top management. The P2 pilot team worked directly with the DOE-Savannah River (DOE-SR) Manager's office to develop a clear, concise policy statement that can be easily understood and a program manual that can be readily implemented by all on-site activities and by all personnel. The trick was making the policy and manual specific enough so that all DOE

organizations were aware of their responsibilities and SRS contractors would have a clear idea of DOE's expectations regarding P2, while leaving the details of how to meet these expectations up to the contractor. The primary purpose of the policy statement is to communicate the DOE-SR Manager's commitment to P2 by establishing a site-wide program. The policy further directs all SRS employees to implement a P2 program using the program manual as guidance while complying with applicable laws, regulations, statutes, executive orders, DOE Orders, and DOE policies. The program manual identifies roles and responsibilities for various DOE-SR organizations. P2 responsibilities apply to all DOE-SR organizations, but individual organizations may have different responsibilities. Some organizations have little or no operational responsibilities and do not generate hazardous waste. These organizations, however, still have P2 responsibilities for energy conservation and non-hazardous waste recycling. Other organizations have greater responsibilities due to their assigned operations. Table I shows specific responsibilities for each DOE-SR organization.

Fig. 1

Table I

The P2 pilot team developed ten specific objectives to help define and communicate its vision of the SRS P2 program. The following objectives are based on DOE-wide objectives established in the 1994 Pollution Prevention/Waste Minimization Crosscut Plan (1) and DOE Pollution Prevention Policy Memorandum (2):

Establish, under a central DOE-SR authority, a comprehensive P2 Program complete with the necessary infrastructure to reduce environmental releases to air, surface water, groundwater, and land and to conserve energy and water in a cost effective manner.

- Reduce total releases of toxic chemicals to the environment (including off-site transfers for treatment and disposal) to support DOE's compliance with Executive Order 12856, "Federal Compliance with Right-to-Know Laws and Pollution Prevention Requirements" (3), which calls for a 50 percent reduction (DOE-wide) by December 31, 1999.
- Reduce the generation of low-level, high-level, transuranic, hazardous, and mixed waste streams each year. Establish quantitative, yet realistic, source reduction and recycling goals that are based on appropriate production levels or activity levels.
- Reduce low-level waste disposal through source reduction, recycling, and volume reduction to meet annual DOE-SR allocations.
- Reduce disposal of sanitary waste by using source reduction techniques and maximizing the use of existing recycling programs.

Incorporate P2 into detailed facility-level budgets and plans, including both project-specific and programmatic planning documents

Establish the necessary infrastructure to support and promote P2 activities. The infrastructure will include the following items:

- Waste generation and environmental release baselines
- Material inventory tracking system
- Standardized, real-time, computerized tracking system for waste generation and environmental releases
- Waste manifest system
- Waste generator fee system
- Life-cycle cost determinations

Develop prioritized short- and long-term goals. Achievements are facilitated by using a computer-based waste tracking system that uses standardized units and annual milestones.

Incorporate P2 into planning, operations, and design activities.

Perform P2 opportunity assessments. Prioritize potential options on the basis of the most significant P2 potential, technical feasibility, and highest return on investment.

Modify procurement practices to promote P2; reduce the purchase of toxic and hazardous materials to the lowest practical level; incorporate the requirements of Executive Order 12843, "Procurement Requirements and Policies for Ozone-Depleting Substances" (4); and implement Executive Order 12873, "Federal Acquisition, Recycling, and Waste Prevention" (5) by using the Federal government's purchasing power to help stimulate the market for recycled materials.

Integrate P2 into the SRS employee work ethic through training, procedures, performance indicators, and incentive programs.

Develop and maintain a technical information exchange network for technologies, activities, practices, alternative processes, and chemical substitutions that is accessible by all SRS organizations and other DOE sites.

Incorporate P2 plans and activities into SRS public outreach and community involvement forums.

Establishing a Pollution Prevention Council

Each Assistant Manager has a designated point-of-contact representing his or her organization on the council. These individuals participate in council meetings to address P2 matters of SRS-wide significance. The DOE-SR P2 Council is empowered by the DOE-SR Manager to act as an advising body to facilitate the development, coordination, and implementation of the comprehensive SRS-wide P2 program and policy. The DOE-SR P2 Council was not established to exercise oversight on member organizations or to alter existing Assistant Manager authorities with respect to P2 activities under their direction. The ultimate responsibility for the SRS P2 program remains with the Assistant Manager for Environmental Restoration and Solid Waste.

The DOE-SR P2 Council ensures the timely completion of SRS-wide P2 activities that are recommended by the DOE-HQ Executive Board and such other direction as the DOE-HQ Executive Board may provide. Council members exercise their individual authorities collectively as an advising body to set P2 priorities, identify resources and expertise, monitor progress, and resolve issues to ensure the continuing effectiveness of the P2 program. Moreover, council members ensure that their respective organizations fully participate in the SRS P2 program. The DOE-SR P2 Council communicates with the DOE-HQ Executive Board through its chairman, the DOE-SR Manager, to achieve management objectives defined by the DOE pollution prevention crosscut plan (1). The DOE-SR P2 Council implements all further directions provided by the DOE-HQ Executive Board. Council meetings are called by the Chairman and are held on a regular basis. In addition, the Chairman calls special meetings to discuss and resolve stakeholder issues or if the DOE-HQ Executive Board requires actions on an expedited basis. The council establishes internal operating procedures for conducting meetings and schedules for holding meetings. The council extends invitations to representatives of other DOE Offices, DOE-HQ, other agencies, or industry to attend meetings, when appropriate.

Successfully Integrating Pollution Prevention Criteria Into

Contracting Mechanisms

Naturally, the P2 program would not be successful without contractor support. The P2 pilot team ensures that realistic and achievable goals are placed into award fee criteria for each evaluation period. The M&O contractor award fee is the contracting mechanism that allows the contractor to earn a profit if certain DOE-SR goals or criteria are met. An example of award fee criteria is the documented reduction of low-level radioactive solid waste disposal at SRS by ensuring that no more than 70 percent of the annually-allocated disposal space is actually used during the year. This award fee criteria will force generators to find ways to reduce the volume of low-level waste sent for disposal and it will increase the life span for SRS low-level waste disposal facilities.

The P2 pilot team modified the contract with the existing M&O contract to ensure that affirmative procurement requirements were being met. Affirmative procurement basically uses the buying power of the federal government to support industries that manufacture products that are made with recycled material. Used oil, as an example, can be purchased by a recycler, recovered, treated, and made available for purchase as recycled oil. Affirmative procurement authorizes purchasing agents for the federal government to gives a preference to those vendors that sell oil, for example, that has been recycled. Under normal circumstances, purchasing agents are not allowed to give a vendor any type of preference. By modifying the M&O contract, the P2 pilot team gave SRS contractors the ability to meet the requirements in Executive Order 12873 (5), which identifies a preference for purchasing certain products made from recycled materials. This award fee criteria is a way of closing the loop on the recycling industry because it creates a market for the materials that are being recycled in increasing amounts across the country.

In addition, DOE's expectations are further delineated in the SRS Annual Operating Plan (AOP) and the Program Execution Guidance (PEG). The award fee criteria are evaluated and updated twice per year, while the PEG and AOP undergo annual updates. Together, the award fee criteria, PEG, and AOP provide a mechanism for updating both DOE and the contractors on expectations and progress toward achieving SRS's comprehensive P2 program.

Developing a Technical Assessment Guide

DOE has developed a contractor assessment program to help DOE evaluate contractor progress in implementing the SRS P2 program. A three-year plan was developed to evaluate the contractor's implementation of the P2 program. In 1995, the P2 pilot team has performed over 30 assessments using expertise from several DOE-SR organizations and a technical support contractor. This teamwork approach is a primary reason for the successful implementation of the comprehensive SRS P2 program to date. DOE has identified numerous achievements, especially in waste reduction and treatment, and several areas for further development.

One of the best success stories at SRS is the Excess and Salvage Program. This program diverts waste materials to salvage vendors, government excess material exchanges, government donation programs, and public auctions. Funds obtained from the sale of salvaged items are provided to DOE. The Excess and Salvage Program has more than quadrupled the amount of salvaged waste from fiscal year 1992 to fiscal year 1995. Cooperation among many SRS organizations is a key element to the program's success. This program is well-known and widely accepted at SRS, so future growth is expected.

CONCLUSION

In under 12 months, the P2 pilot team has successfully built a strong foundation for the comprehensive SRS P2 program by developing a site-wide policy and manual, assisting with the creation of the SRS P2 Council, integrating P2 program goals and objectives into contracting mechanisms, and developing and implementing an assessment schedule. Significant activities that are currently being implemented or pursued include a waste manifest system, waste generator fees, a subcontractor waste treatment cost allocation system, and generator waste tracking program. The pilot team will build on this foundation as it continues to implement a comprehensive P2 program at SRS.

ABSTRACT

Lawrence Livermore National Laboratory (LLNL) has developed a portable screening system that will recondition radioactively contaminated gravel in the field. The separation technique employed by this system removes dirt, contaminated debris, and other fine particles from gravel. The separation process can be used on gravel or other comparable material ranging in size up to 2.5-cm (1-in.) in diameter. The particle size of dirt and debris removed is variable. For pea gravel, the particles removed can vary from 38 mm-1 cm (3/8 in.).

At LLNL, gravel is used in conjunction with the experimental testing of explosives to reduce shock wave propagation. The gravel surrounds the experimental device and buffers the energy generated from the explosion. During an explosion, some of the gravel is broken down into small particles and mixed with contaminants. Contaminants in the used gravel

originate from metal sheathing and other parts comprising the experimental device. These contaminants may consist of radionuclides (primarily depleted uranium) and metals (e.g., beryllium, copper, and zinc) that are considered hazardous by the State of California when disposed. The small particles generated during the explosion mix with the gravel and collect in the void space between the gravel. The removal of void spaces increases the aggregate material compressive strength and reduces the gravel's effectiveness for shock wave reduction. Reconditioning removes the small particles and some contaminants and restores the gravel's effectiveness for shock wave reduction.

The paper presents the process that conveys contaminated material into the screener system, sprays the material with recycled water or other mild cleaning chemicals, and separates the particles based on size. Particles greater than a specified size are discharged out of the screener separator and recycled back into use, thereby reducing the amount of mixed waste generated and minimizing the need for new gravel. An array of smaller particles are discharged into drums and, if desired, reused in other applications. The fines or silt are flushed out of the separator with the water and are removed from the water and consolidated into a drum with the use of a hydrocyclone separator and drum decant system. Because the water in the spray system is recycled, minimal makeup water is needed. The system monitors pH and total dissolved solids (TDS) and, when undesired levels of pH or TDS are reached or when suspended solids could result in clogs, the spray system can be purged and refilled.

INTRODUCTION

Lawrence Livermore National Laboratory performs experimental testing of explosives at designated remote locations in an area called Site 300. An experimental device is used for the explosive test. The construction of the experimental device varies, but it usually has a metal sheath and often contains depleted uranium, beryllium, copper, and zinc. Experimental devices can also contain lead. The experimental testing at Site 300 is conducted on gravel pads. The gravel on the pad is approximately 1.3 cm (0.5 in.) in diameter, with the smallest particles being 2 mm in diameter. The gravel is used to reduce shock wave propagation during explosive testing.

The experimental device is buried with gravel, which surrounds it and buffers the energy generated from the explosion. During the explosion, the gravel is broken down into smaller particles and mixes with contaminants. Contaminants in the used gravel originate from metal sheathing and other parts comprising the experimental device. These contaminants may consist of radionuclides (primarily depleted uranium) and metals (e.g., beryllium, copper, zinc) that the State of California considers hazardous to dispose of.

After an explosive test, a higher percentage of the gravel material is 2 mm or smaller. These small particles generated during the explosion mix with the gravel and reduce its effectiveness for shock wave reduction. With repeated use of the gravel, a buildup of contaminants and radioactivity is deposited on the gravel. When the contaminants are beryllium, copper, and zinc, the buildup results in the potential generation of low-level radioactive waste with California hazardous metals. When the contaminants are lead and chromium, the buildup results in the potential generation of Resource Conservation and Recovery Act (RCRA) mixed waste. See Table I for a listing of the state and federal

regulated hazardous metals and their regulatory levels. To avoid the possibility of generating mixed waste after it is used, the gravel must be removed from the pad and either discarded or reconditioned.

To determine whether or not a waste is hazardous, the State of California requires a leach test and/or a total waste analysis using the California Assessment Manual Wet Extraction Test (CAM-WET) for Soluble Threshold Limit Concentration (STLC) and for Total Threshold Limit Concentration (TTLC). The STLC is a extraction method that measures the amount of extractable substances in the material. The TTLC provides a total analysis of the material by determining which analytes are present and their concentrations. These tests are used instead of the federal Toxicity Characteristic Leaching Procedure (TCLP).

Before we developed the gravel reconditioning method, the gravel was removed from the gravel pad when it no longer reduced shock waves effectively and was placed into disposal containers, sampled, and analyzed. Depending on the analysis, the waste was disposed of as low-level radioactive waste or low-level radioactive waste with California hazardous metals. The contamination had not built-up enough to consider the waste RCRA mixed waste. The amount of gravel removed averaged around 4,536kg (10,000 lb) per explosive test, and about 4,536 kg (10,000 lb) of clean makeup gravel was added to replenish the pad.

Using our reconditioning method, the small particles (particles less than 3.7 mm) and some contamination are removed from the gravel. Now, up to 85% of the gravel (3,855 kg or 8,500 lb per test) is reconditioned and placed back into use. About 680 kg (1,500 lb) of clean makeup gravel is needed to replenish the pad after an explosive test.

Table I

TREATABILITY STUDIES

We performed small-scale treatability studies to determine if screening would be an effective way of reconditioning gravel. A multitiered bench-top sieve unit (or screener) with an assortment of screen mesh sizes was used in the experiments.

Dry Screening

The first experiment was performed on dry gravel to determine the particle distribution of the gravel so that we could determine the optimal screen size(s) for retaining undersized particles. Six screens were selected with the sieve mesh ranging from 8 to 400 (i.e., sieve openings ranging from 2.8 mm to 0.037 mm). Dirty gravel was added to the top tray and allowed to shake in the sieve unit for 10 minutes. After shaking, the amount of gravel in each tray and in the bottom of the pan was calculated. See Table II for results of the test.

Table II

The design for the gravel reconditioning process made use of two screens: one screen for removing coarse fines from the gravel and the other for removing silt and small fines from the coarse material. Table II indicates that particles less than 2 mm account for 4.1% of the total gravel. When using a screen with a larger opening (i.e., No. 8 mesh), only a small increase of particles was noted, so we determined that No. 10 mesh screen could adequately remove coarse fines from the gravel. Both the No. 200 mesh and No. 325 mesh screens could adequately remove silt and small fines from the coarse material; however, the No.325 mesh screen is constructed of fine wires and is very fragile. Because the No. 325 mesh screen tears easily and is expensive ($300 compared to $186) to replace, we decided to use the No. 200 mesh screen.

Wet Screening

In the second experiment, we tested wet gravel to determine the effectiveness of spraying the gravel with water while screening and calculated the moisture content of the wet gravel removed from the unit. The sieve unit was adapted with a recirculating water system. Only two trays (No. 10 mesh and No. 200 mesh screens) were added to the sieve unit. The dirty gravel was added into the top tray of the sieve unit, the water recirculation system was turned on, and the unit was allowed to shake for a specified period of time. After shaking, the amount of gravel was calculated in each tray and for the bottom of the pan. See Table III for the wet screening results.

Table III indicates that particles less than 2 mm account for 9.6% of the total gravel. Compared to dry screening (where particles less than 2 mm account for 4.1% of the total gravel), we determined that wet screening is more effective at removing smaller particles from the gravel. In addition, the amount of water removed from the system when the gravel is discharged is small. The water makeup rate for both the top tray and middle tray of the wet gravel is 3.8%.

Table III

Test for Cleaning Ability

We also studied how well wet screening could clean. We performed the wet screening operation described earlier several times using water and twice using a nitric acid solution (pH 2) on contaminated gravel. Samples of the gravel in the top tray, middle tray, and bottom pan were taken and analyzed. The test results for gravel washed with water are shown in Table IV.

Table IV

The analyses shown in Table IV are based on the State of California's leach test and total waste analysis. The differences between the Federal (TCLP) and the California State (STLC) leaching tests are subtle. The California State leaching test is more rigorous and, therefore, provides us with more conservative results. The differences in these tests are summarized in Table V.

Table V

The STLC test was performed on the larger pieces of gravel (particles >2.0 mm) to test the effectiveness for reducing leaching, and the TTLC test was performed on the sludge and silt (particles 2.0 mm) to determine the type and concentration of material that was removed by the screening process.

Table IV shows that some beryllium, chromium, copper, lead, and zinc was removed; however, when performing a mass balance on each contaminant, the exact amounts or percentages could not be calculated with the limited number of samples taken. The gravel is heterogeneous, which made it difficult to collect representative samples. Future samples will be taken of the gravel, sludge, silt, and fines. These sampling results may help us determine how well wet screening cleans the gravel.

DESIGN REQUIREMENTS

The full-scale Gravel Reconditioning Unit was designed to meet the following criteria:

- A gravel process rate of approximately 5,443 kg (12,000 lb) in a 6-hour day or 907kg/h (2,000 lb/h)
- Ability to feed gravel to the screener with a front-end loader if conveyors are not used

Hopper loading minimized to 2-3 times a day (i.e., gravel capacity of between 1.2-1.8 m3 (42-63 ft3) if a hopper is used)

Skid-mounted unit, transportable by a flatbed truck, so that it can be moved from one gravel pad to another

Ability to withstand an outside environment and outdoor location

Portable so that it can be operated in the field on the gravel pad at a distance of 30 m (100 ft) from any electrical or water source

Easy to operate and requiring minimal set-up, operating, and shutdown effort

No use of an air compressor in its operation

LLNL seismic criteria at all times

Design and fabrication cost of less than $100,000 for the unit

Design, procurement, and fabrication schedule of 7 months

Design Overview

The Gravel Reconditioning Unit is a portable skid-mounted unit used to recondition gravel. The gravel reconditioned by the unit is restored to its original size with its original dampening effectiveness and is placed back into use. The Gravel Reconditioning Unit contains a feed delivery system, screen separator unit, water reservoir, water recirculation system, rinsate separation system, and control panel. A layout of the gravel reconditioning process is shown in Fig. 1.

Fig. 1

Feed Delivery System

The feed delivery system contains a hopper, slide control valve, and flexible connector. The feed delivery system uses a front-end loader to place the gravel into the hopper. The hopper feeds to the screen separator unit that is mounted on the skid.

For ease in construction, the hopper was designed as an inverted pyramid with a rectangular opening and base. The hopper was constructed out of 304 stainless steel with all exposed seams welded. The overall dimensions of the Gravel Reconditioning Unit is 1.7 m wide x 2.4 m long x 2.7 m high (5.5 ft x 8 ft x 8.9 ft).

The bottom opening of the hopper is located directly over the inlet to the screen separator unit. The slide control valve is mounted under the hopper and regulates the amount of gravel entering the screen separator unit. The slide control valve is a manually operated slide valve. With a little effort, the manual valve can be shut against a full hopper of gravel.

The flexible connector is mounted at the bottom of the slide valve and is connected to the screen separator unit. The connector is flexible so that it can move with the screen separator when it vibrates and can be lifted off easily to change out screens.

Screen Separator Unit

The screen separator for the Gravel Reconditioning Unit is a commercial unit used for wet classification (i.e., solid classification in a liquid medium). The screen separator is cylindrical, has a screen diameter of 0.76 m (30 in.), and is constructed out of stainless steel. The screen separator has two screens and antiblinding features to dislodge small particles from the screen. The sieve mesh for the screens were originally No.10 mesh and No. 200 mesh, but were increased to No.6 (3.7 mm opening) mesh and No. 18 (1 mm opening) mesh to allow better drainage of liquid through the screen.

The screen separator has one inlet at the top of the screen separator, three discharge ports, and a spray system. The spray system washes the

gravel as it enters into the screener. To prevent incoming gravel from damaging the screen, a velocity breaker (strike plate) was installed on the screener lid. The top discharge port is for effluent gravel (particles >3.7 mm), the middle discharge port is for effluent sludge (particles 3.7 mm and >1 mm), and the bottom discharge port is for the effluent silt, fines, and water. The top discharge port discharges clean gravel in to a collection container, the middle discharge port discharges the effluent sludge in to a 208-L (55-gallon) waste drum, the bottom discharge port discharges the effluent silt, fines and water into the water reservoir.

The screen separator uses a three-dimensional inertial vibratory motion to separate particles by size. The screen separator vibrates horizontally, vertically, and tangentially. The control for gravel flow in the unit is adjustable by increasing and/or decreasing the mass of the top and bottom eccentric weights and the increasing or decreasing the lead angle of the bottom eccentric weight. Increasing the bottom eccentric weight increases the vertical component of motion, increasing the top eccentric weight increases the horizontal throw and cause oversized material to discharge at a faster rate, and increasing the lead angle of the bottom eccentric weight imparts a spiral motion of the particles on the screen. If gravel requires additional cleaning, the lead angle of the bottom eccentric weight is increased to keep the gravel on the screen longer.

Water Reservoir

The silt, fines, and water out of the bottom discharge flows into a water reservoir that is constructed out of stainless steel, has a total capacity of 566 L (150 gal), and an average operating volume of 330 L (87 gal). Makeup water is also introduced in the water reservoir. The discharge for the silt solution is at the bottom of the water reservoir. A hinged lid is mounted on top of the reservoir for easy cleanout. A mixer and instrumentation for monitoring pH, conductivity, high water level, low water level, and high-high water level are mounted to the water reservoir to monitor conditions of the water.

Water Recirculation System

The water recirculation system consists of a pump, valves, and piping. The system is designed to process the reservoir water through the rinsate separation system and recirculate it back into the screener separator. The system was designed to the maximum flow rate and pressure requirements of the spray nozzles. The pump is designed so that it doesn't pulsate because pulsating flows cause interferences with the rinsate separation process. The pump chosen is a multistage centrifugal pump.

The valves and piping are designed to meet high system working pressures and constructed out of material that is protected against outdoor environments (ultraviolet radiation). The valves and piping used is schedule 80 chlorinated polyvinyl chloride (CPVC).

In addition to the valves that direct and regulate flow, an over pressure relief valve and pump bypass valve was installed to prevent over pressuring the system. A flow meter was also installed on the water recirculation line to monitor the flow rate of the recirculated water.

Rinsate Separation System

The rinsate separation system consists of a hydrocyclone separator, motor-operated ball valve, purge diffuser, and drum decant system. The rinsate separation system is installed in the water recirculation system

to remove silt and fines from the recirculated water. The solid-free water is discharged out the top of the hydrocyclone separator and into the screen separator. The solids are discharged out the bottom of the hydrocyclone separator and into a 208-L (55-gal) drum. Liquid from the 208-L (55-gal) drum is decanted off and gravity fed into the water reservoir.

The solution pumped from the water reservoir enters the hydrocyclone separator tangentially, which sets up a circular flow. The solution is then drawn through tangential slots and accelerated into the separation chamber of the hydrocyclone separator. Centrifugal action tosses particles heavier than the water to the perimeter of the separation chamber. The particles drop along the perimeter of the cyclone separator and settle into the collection chamber. The solid-free water is drawn up the separator's vortex, up through the separator's outlet, and into the screen separator. Due to high system pressures, a purge diffuser was installed on the hydrocyclone separator discharge line to prevent inadvertent spraying of liquid.

The drum decant system, which consists of a drum shroud with baffle plate and a discharge line to the water reservoir, is attached to the 208-L (55-gal) drum. The gasketed drum shroud is clamped to the top of the drum and allows the water level to raise past the height of the drum without leaking out. As the discharged material (solids and water) fill the 208-L (55-gal) drum, the solid material tends to settle to the bottom of the container while the lighter material remains on the top. When the water reaches the discharge port, the water gravity flows into the water reservoir. The drum decant system minimizes the amount of makeup water to be added to the system, minimizes the amount of liquid waste to treat, and maximizes the solid holding capacity in the drum.

Control Panel

All controls for the Gravel Reconditioning Unit are located on a control panel. The frequency and duration for purging the hydrocyclone separator are also adjustable from within the panel. The panel is a NEMA 4 enclosure, and all controls are weather resistant and rated for outdoor use. The lights and controls on the control panel are visible from outside the enclosure. A crash button and main disconnect are also mounted on the control panel.

CONCLUSIONS

The Gravel Reconditioning Unit is an inexpensive, easy-to-use, low maintenance, portable, and effective way to recondition gravel. Applying the Gravel Reconditioning technique to the gravel on the gravel pads at Site 300 will reduce the amount of low-level radioactive waste, low-level radioactive waste with California hazardous metals, or RCRA mixed waste generated.

The Gravel Reconditioning Unit was designed and fabricated in 8 months for less than $100,000. Testing began in January 1995 and full production cleaning commenced May 1995. Prior to the construction of the Gravel Reconditioning Unit, gravel from past explosions were contained in disposal boxes to await shipment and disposal. Since the late 1980's, a backlog of 142 disposal boxes (644,000 kg) of used gravel have accumulated. To date, over 10% (64,400 kg) of the backlog gravel has been reconditioned.

In an 8-hour period approximately 4,535 kg (10,000 lb.) of gravel is processed with up to 85% by weight (or 3,855 kg) of the large gravel being recycled. The remaining 15% of the material is contained in either

a disposal box or 208 Liter (55-gallon) drum to await shipment and disposal. The water reservoir is changed out approximately once a week, due to silt build-up and higher level of contaminants in the water. The handling and treatment of the waste water generated by the reconditioning process is a routine practice for LLNL. The waste water can be treated at the Tank Farm and (when analytical results indicate that it meets acceptance criteria) emptied into the LLNL sewer (ultimately to reach the city water reclamation plant). If necessary, the silt and sludge waste generated by the reconditioning process can also be treated (stabilized) at LLNL.

This gravel reconditioning procedure results in a cost benefit of approximately $42,000 for processing and disposing of the backlog gravel. This includes a $1,800/day savings in disposal costs but, does not include savings in costs associated with the procurement and delivery of new gravel. Factoring in the cost of the unit, the savings in treating the backlog material is greater than 10%. After the cost of the unit has been realized, the savings increase to greater than 30%.

Lockheed Idaho Technologies Company*

ABSTRACT

In May of 1994, Lockheed Idaho Technologies Company (LITCO) in Idaho Falls, Idaho and subcontractors began development of the System Cost Model (SCM) application. The SCM estimates life cycle costs of the entire U.S. Department of Energy (DOE) complex for designing; constructing; operating; and decommissioning treatment, storage, and disposal (TSD) facilities for mixed low-level, low-level, and transuranic waste. The SCM uses parametric cost functions to estimate life cycle costs for various treatment, storage, and disposal modules which reflect planned and existing waste management facilities at DOE installations. In addition,

SCM can model new TSD facilities based on capacity needs over the program life cycle. The user can provide input data (default data is included in the SCM) including the volume and nature of waste to be managed, the time period over which the waste is to be managed, and the configuration of the waste management complex (i.e., where each installation's generated waste will be treated, stored, and disposed). Then the SCM uses parametric cost equations to estimate the costs of pre-operations (designing), construction, operations and maintenance, and decommissioning these waste management facilities. The SCM also provides transportation costs for DOE wastes. Transportation costs are provided for truck and rail and include transport of contact-handled, remote-handled, and alpha (transuranic) wastes.

A complement to the SCM is the System Cost Model - Risk (SCM-R) model, which provides relative Environmental, Safety, and Health (ES&H) risk information. A relative ES&H risk basis has been developed and applied by LITCO at the INEL. The risk basis is now being automated in the SCM-R to facilitate rapid risk analysis of system alternatives. The added risk functionality will allow combined cost and risk evaluation of EM alternatives.

INTRODUCTION

The System Cost Model (SCM) was designed based on the cost knowledge developed for the Waste Management Programmatic Environmental Impact Statement (WM PEIS). The WM PEIS demanded that a consistent life cycle cost system be developed and utilized for cost analysis and data input for risk assessments and socioeconomic analysis. The WM PEIS analyses were successfully performed on various waste management alternatives for low-level waste (LLW), mixed low-level waste (MLLW), and transuranic waste (TRU). The engineering basis for the SCM was derived from WM PEIS technical reports: Waste Management Facilities Cost Information for Low-Level Waste (1), Waste Management Facilities Cost Information for Mixed Low-Level Waste (2), Waste Management Facilities Cost Information for Transuranic Waste (3), and Waste Management Facilities Cost Information for Transportation of Radioactive and Hazardous Material (4). This cost information as programmed in the SCM provides DOE with a tool to perform waste management sensitivity analysis on the Baseline Environmental Management Report and Technology Development applications.

Sponsors

Lockheed Idaho Technologies Company's (LITCO's) Technical Support Program with contractor assistance from MK-Environmental Services (MKES) developed the System Cost Model (SCM) at the request of the Department of Energy's (DOE's) Office of Waste Management (EM-30). Further development and refinement of the SCM for technology development applications is sponsored by the DOE Office of Science and Technology.

What Is the SCM?

The SCM estimates life cycle costs of the entire U.S. Department of Energy (DOE) complex for designing; constructing; operating; and decommissioning treatment, storage, and disposal (TSD) facilities for LLW, MLLW, and TRU (including mixed TRU). The SCM uses parametric cost functions to estimate these life cycle costs. Parametric cost functions develop costs for various treatment, storage, and disposal modules which reflect planned and existing facilities at installations. In addition, SCM can model new facilities based on capacity needs over the program life cycle. The user can provide input data (default data is included in the SCM) including the volume and nature of waste to be managed, the time

period over which the waste is to be managed, and the configuration of the waste management complex (i.e., where each installation's generated waste will be treated, stored, disposed, and transported). Then the SCM uses parametric cost equations to estimate the costs of the following program life cycle phases of waste management facilities.

Pre-operations__Pre-operations pertain to the studies and bench scale test costs, demonstration costs, and operations budget funded activities (conceptual design, safety assurance documentation, permitting, preparation for operation, and project management).

Construction costs__Construction costs include title I and II design, inspection, project management, building construction (including indirect costs), equipment (including indirect costs), construction management, and contingency costs related to facility construction.

Operation and Maintenance__Operations and Maintenance relates to operating labor, utilities, material, maintenance, and other costs including reserve and contingency costs.

Decommissioning__Decommissioning pertains to manpower, surveillance and maintenance, assessment and characterization, environmental documentation review, operations, closure, and post-closure monitoring.

Examples of Current Uses for the SCM

Baseline Environmental Management Report. The SCM has been used in FY-95 and FY-96 to support the preparation of the Waste Management Portion of the Baseline Environmental Management Report (BEMR). In order to support BEMR modeling efforts, the SCM has been calibrated for each of the six major DOE sites. The calibration is done so that SCM can simulate the BEMR cost estimates for these sites and represent their existing and planned waste management facilities in the complex-wide BEMR modeling activities. DOE then uses the BEMR treatment option within the SCM to conduct sensitivity analysis.

To increase the accuracy of the model for BEMR analysis activities, the SCM was calibrated to the baseline plans at the six major DOE installations (i.e., Hanford Site, Idaho National Engineering Laboratory, Los Alamos National Laboratory, Oak Ridge Reservation, Rocky Flats Environmental Technology Site, and the Savannah River Site). These six sites represent over 80% of the waste management costs within the DOE complex. The calibration effort included site visits and intense data gathering to:

- Customize SCM with site-specific input data;
- Calibrate modeled estimated operation and maintenance costs to the sites cost for existing treatment, storage, and disposal facilities;
- Calibrate algorithms for studies and bench scale test, demonstration, construction, and operations to the site's assumptions for facility design, construction, and operations costs; and
- Develop cost relationships to derive a total site waste management cost (including program management and other site overheads) from modeled SCM facility costs.

Technology Development. The SCM will be used in FY-96 to perform technology assessments on thermal and non-thermal treatment systems. The SCM will aid Technology Development in estimating system and sub-system cost variations due to: changes in waste streams loading, schedules (e.g., long-term storage, varying operation periods), pre-treatment requirements (e.g., sorting, characterization, handling), waste form variations on disposal requirements, and transportation (e.g., containers, packaging).

Examples of the type of analysis that can be performed using the SCM for Technology Development include:

Evaluation and comparison of new thermal treatment technologies and non-thermal (washing) technologies;

Comparison of effects from final waste form (e.g., grout, glass) on transportation and disposal costs and risks;

Trade-offs between waste storage costs and risks versus improved technology performance;

Advantages of combined processing of similar wastes (e.g., alpha LLW, alpha MLLW, mixed TRU waste);

Optimize performance of treatment systems (e.g., reducing treatment effluents, reducing sorting and characterization).

SYSTEM COST MODEL FUNCTIONALITY

The SCM system architecture enables new features to be easily added as the product matures. A high-level, functional view of SCM architecture is shown in Fig. 1.

Fig. 1

The SCM architecture illustrates the partitioning of the model structure into three distinct components: Inputs, System, and Outputs. The Inputs define the model parameters that are required to execute calculations of the system. The System components consist of the calculation engines required to produce the desired outputs. The Output component provides the desired screens and reports that contain the results from the system calculations and provide a record of the input parameters. Each of these components are described in more detail in the following sections.

INPUT INFORMATION

Data from the five required categories (waste loads, TSD scenarios, site schedules, and facility profiles) must be completed for the program to function. It is up to the user's discretion whether to make any changes to the five optional categories (work breakdown structure (WBS) scale factors, other site costs, cost factors, charge backs, and inflation factors). Default data for these five optional categories has been pre-loaded into the SCM.

Waste Load Information

Matrix categories, also termed waste stream fields, are categories of waste that are distinguishable by their origin, physical state or form, composition, radioactivity, or a combination of these characteristics. The waste loads in the SCM are identified by 32 unique matrix categories which are consistent with the classification scheme used in the Mixed Waste Inventory Report. The categorization of wastes also allows summation of common wastes across waste types (i.e., LLW, MLLW, TRU). Waste loads provide the foundation for the SCM. Facility costs are calculated from algorithms relating cost to capacity, and capacity is derived from waste loads. Waste loads are required for a given waste type (low-level waste, mixed low-level waste, transuranic waste) in order to create a specific case. If waste loads are not defined for any of the waste types, calculations cannot be executed. Waste loads that are in inventory are termed legacy waste. Generated annual waste contributes to the overall waste loads for the SCM case scenario.

Treatment, Storage, and Disposal Scenarios

The user defines the destination of waste for treatment, storage, and disposal (TSD) locations by site (onsite, offsite). The waste can be "split" by the 32 waste matrix categories to go to different DOE sites for treatment, storage, or disposal. For onsite treatment, SCM offers

optional treatment schemes that make use of different technologies aimed at meeting various treatment objectives.

Site Schedules

Once the quantity of waste and the treatment, storage, and disposal scenarios have been entered, the SCM allows the user to edit the scheduling of new treatment, storage, and disposal facilities at a site. Site schedules can be manipulated for start and stop dates, and durations of major cost elements (e.g., preoperation, construction, O&M, D&D). Shipping schedules are used to establish when waste moves from storage to treatment. The scheduling information controls storage requirements and will affect the amount and scheduling of costs.

Facility Profiles

The SCM's database contains information about the known DOE site waste management facilities, based on the information available at the time of the release of the SCM application. This information includes capacities, operating periods, and any known upgrade costs or O&M costs. The SCM also contains information for the modules represented by the facilities and the waste type dedications (what kind of waste the module can process).

Optional User Input Data

In addition, the user is allowed to select, enter, or change the following data:

- Offsite DOE treatment unit costs
- Treatment options for each waste type (e.g., Base Case, BEMR Calibrated, Nonflame,)
- Transportation (rail/road)
- Commercial unit costs
- Existing or planned DOE facility cost information
- Site-specific cost factors and labor rates
- Cost escalation factors

User Input Options

The model provides a default set of parameters that SCM users may use to select the site, facility, waste type, etc. The system was designed so that very little input data is required from the user. The SCM contains and provides the following internal reference data:

- Cost data based on Waste Management Facility Cost Information reports;
- Generic schedule data;
- Existing and planned/approved facility capacity and operating parameters (based on latest BEMR);
- Minimum and maximum scaling factors for parametric cost/capacity equations;
- Transportation miles and costs/mile;
- Standard operating parameters (such as years of operations and maintenance);
- Module flow factors (site-specific processing schemes).

Case Changes Can Be Saved

If the user selects to change the data input elements as defined above, the modified data can be saved in scenarios called cases. An SCM user can access the saved cases in the future and perform additional modifications. The SCM cases can be copied to or from different personal computers (PCs) via floppy diskettes or a network media. The user can select different cases and merge these cases into a single case.

SYSTEM CAPABILITIES

The SCM provides the general capability to calculate the total life cycle costs by module for the LLW (alpha, non-alpha, and remote handled), MLLW

(alpha, non-alpha, and remote-handled), and TRU waste / MTRU waste (contact and remote handled). The SCM user can chose between different treatment options for each waste type. The following table provide the treatment options that SCM supports for the 3 major waste types.

Table I

System Calculations

The System calculations include the following:

- Full-time equivalent (FTE) manpower estimates for each module by WBS
- Cost and FTE annual and cumulative profiles for the three selected waste types
- The administrative and support modules are automatically sized and costed
- Cost by general module/facility type (pre-treatment storage, treatment, storage, and disposal)
- Cost by new facilities versus existing facilities
- Portable treatment or commercial treatment options
- Fixed minimum cost of facility modules for waste loads less than the defined module capacity range
- Summation of DOE complex cost roll-ups of all DOE sites
- Integrated transportation costs (combination of road and rail)
- Calculations to allow facility capacity versus operating period manipulations

Unique System Features

The System also has unique capabilities which allow waste shedding, which allows a site to distribute the same waste stream to several sites including a commercial designation. Disposal shedding also allows the generating site to distribute waste treated at one treatment location to multiple disposal sites. A user can also designate offsite processing for treatment and/or disposal of waste. In past versions, the SCM automatically built a new facility that would be decontaminated and decommissioned. To more accurately provide full life cycle costs, a finite lifetime constraint is placed on all new facilities (default of 30 years which can be configured by the user up to 50 years). The SCM automatically calculates pre-treatment storage based on user decisions of the earliest construction startdate of new facilities and waste scheduling. The system also automatically calculates post-treatment storage based on availability of disposal facilities. Waste storage or disposal costs can also be charged back to the generating sites. This charge is based on the quantity of waste and either a calculated unit rate or a user-provided unit rate.

The total life cycle costs for each module are organized based on the work breakdown structure (WBS) outlined in Table II.

Table II

OUTPUT CAPABILITIES

The SCM provides the following reporting capabilities:

- Prints user-selected case summary or site detail reports; case summary, site detail, or case comparison graphs; and case Gantt charts.
- Preview option for viewing reports on the screen before printing reports.
- Data exports into text database, spreadsheet, and word processing format.
- Present data in tabular and graphical formats (Fig. 2).

Fig. 2

RELATIVE RISK ANALYSIS CAPABILITIES

The System Cost Model - Risk (SCM-R), a prototype version of the SCM, will provide relative Environmental, Safety, and Health (ES&H) risk information. A relative ES&H risk basis has been developed and applied by LITCO at the INEL. The risk basis is now being automated in the SCM-R to facilitate rapid risk analysis of system alternatives. The added risk functionality will allow combined cost and risk evaluation of EM alternatives. The simplified methodology for ES&H relative risk is composed of the following five elements (5):

Element 1 - is the characteristics of the waste type which is composed of quantity of contaminants in the waste type and the specific radio toxicity of the radionuclides and/or the specific chemical toxicity of the hazardous chemicals.

Element 2 - expresses the ease with which the contaminants in the waste type could escape confinement as a result of events or conditions that breach the confinement.

Element 3 - expresses the likelihood, or probability, of loss of waste confinement.

Element 4 - how effectively the released contaminants could be moved by environmental transport processes (e.g., wind, groundwater transport, biotic transport) to receptors.

Element 5 - the presence of human receptors. How frequently workers would be located around the waste type, how many workers would be involved, and how closely they would be involved? How many members of the public are located near the waste type, and how close?

The data inputs for the SCM-R includes several parameters from the cost and FTE calculations. These include technology descriptions, waste forms, schedules, transition and rest states, facility capacities, and DOE site-specific information. Additional risk parameters are included in the SCM-R to define the waste characteristics (i.e., radiological and hazardous profiles), mobility, confinement, stresses, transport, worker and public proximity, and time in states. The relative risk will be output from the SCM-R on a comparative state basis, and on an annualized risk basis.

DELIVERABLE SOFTWARE AND DOCUMENTATION

Software distribution of the System Cost Model is under the control of LITCO and the DOE. System modifications and configuration control are closely maintained by the project. New releases of the SCM consist of the following:

1. SCM Software: The software consists of an executable version of FoxPro which runs stand-alone on an IBM PC (or compatible) under the Microsoft Windows 3.1 environment.
2. Product Description: The SCM Product Description (6) provides the current system description of the model capabilities. The Product Description will be maintained throughout the SCM development cycle to ensure that it is current and accurate. All changes to this document will be done in accordance with the change control procedures established by the WMFCI project manager and LITCO document control.
3. User's Manual: A user's manual will be developed to accompany major releases of the SCM. The manual will provide a basic overview of the software and user instructions. In addition to the user manual, user training and a training presentation may be required.

CONCLUSIONS

This paper has provided a description and overview of the capabilities of the System Cost Model and the System Cost Model - Risk. The SCM calculates life cycle waste management costs based on waste loads. The

SCM is loaded with default information that represents the latest available site-specific data collected in support of the 1996 BEMR. The SCM has been successfully applied to several EM-30 programs. The tool will be refined in the future by addition of the relative risk function (SCM-R), and capabilities to provide technology development analysis.

ABSTRACT

A polymer encapsulation process is being developed at the Rocky Flats Environmental Technology Site (RFETS) for treatment of mixed wastes containing high concentrations of salts, which inhibit the solidification reaction of Portland cement based grouts. Encapsulation using polymers forms a suitable matrix for this type of waste by a micro encapsulation of the waste via a homogeneous mixing process of the polymer and waste. Solidification of actual radioactive and mixed waste in a pilot-scale system will be the first large-scale polymer encapsulation of significant quantities of actual mixed waste within the DOE complex. As part of this program, methods are being identified to collect consumer waste plastic for utilization in the polymer encapsulation of wastes.

INTRODUCTION

The need to treat mixed waste (containing both hazardous and radioactive constituents) to meet regulatory requirements is a problem that is common to many DOE sites. During their many years of operation, Rocky Flats and other DOE sites generated mixed wastes that are now subject to the Resource Conservation and Recovery Act Land Disposal Restrictions (RCRA LDR). LDR regulations require that mixed waste be treated by specific technologies or that final waste forms meet specific treatment standards before they can be considered for disposal at a permitted hazardous waste landfill. Mixed waste must also comply with Department of Transportation shipping standards and acceptance criteria specific to each permitted landfill.

Rocky Flats cannot ship the majority of its mixed waste off site for treatment or disposal because the waste does not meet the regulatory requirements. Also, Rocky Flats does not have adequate treatment facilities in place to produce LDR compliant final waste forms. For these reasons, polymer encapsulation, as one of a suite of treatment technologies, is being developed at Rocky Flats.

Although not as widely used as cementation, polymer encapsulation offers several advantages over cementation, including increased waste loading, increased waste form durability, and insensitivity to variations in waste stream chemistry. Polymer encapsulation is a simple, low temperature process that is relatively easy to permit and implement. Furthermore, waste plastics can be used as the encapsulating medium. This has cost benefits and provides an opportunity to put to beneficial use material that might otherwise be landfilled.

Since polymer encapsulation can be adapted to handle commercial low level and hazardous waste, Kaiser-Hill has entered into an agreement with Rust Federal Services to commercialize the technology. As part of the agreement, Rust will use resources available through its sister company, Waste Management, to investigate the economics of collecting appropriate post consumer plastics for mixed waste treatment.

TECHNOLOGY DESCRIPTION

Mixed waste stabilization using polymers is adapted from existing processes widely used in the polymer industry (1-3). Although the application of polymers to mixed waste differs from private sector applications in the areas of product acceptance criteria and operating conditions, the two applications are very similar. All of the equipment and supplies are commercially available "off the shelf."

Thermoplastic polymers, such as polyethylene, are heated above their melting temperature (110oC), mixed with powdered wastes, and poured into a disposal container, where solidification occurs as the melt cools. No significant chemical interaction occurs between the waste and the polymer. Waste requiring stabilization to meet Toxicity Characteristic Leaching Procedure (TCLP) standards is dried and then encapsulated in polyethylene using a commercially available compounding extruder. The appropriate extruder for this application uses two co-rotating intermeshing screws. Electrical resistance heaters in the extruder barrel and friction introduced by the rotation of the screws melt the polyethylene pellets. Dried waste is fed into the extruder using a down stream side feeder, where the waste encounters molten polyethylene. Kneading blocks and/or pin mixers downstream of the waste feed port mix the waste with the molten polyethylene. A vent port can be used to remove excess moisture and reduce the porosity of the final waste form. The

molten mixture is extruded into the final disposal container, where solidification occurs as the mixture cools.

Rocky Flats also uses thermoplastic extrusion to macroencapsulate radioactive lead and debris wastes. In this case, waste is placed in a basket sized slightly smaller than the disposal container. Molten polyethylene is extruded into the disposal container, filling the annular space between the basket and disposal container as well as voids within the waste.

The treatability studies completed at Rocky Flats indicate that waste loadings of 30 to 80 weight-percent are possible with polyethylene extrusion while still producing an LDR compliant waste form (4-6). Waste loadings of 50 weight-percent are typical for the majority of the mixed waste tested. Depending on the physical characteristics of the waste stream and the maximum achievable waste loading, volume expansion factors vary from -0.5 to +1.5.

Because polyethylene is resistant to most chemicals, polyethylene extrusion is a good option for mixed wastes that are difficult to stabilize using other methods such as cementation or vitrification. Sodium chloride salts, for example, are not soluble in glass and severely inhibit the cement hydration reaction. Since there is no reaction between the sodium chloride and the polyethylene, high waste loading of sodium chloride is achievable in polyethylene. Other salts that are difficult to stabilize in cement or glass but that are compatible with polyethylene extrusion include sodium sulfate, ammonium sulfate, and sodium nitrate.

Through its wide usage, the durability of polyethylene has been clearly demonstrated. Particularly significant is the fact that polyethylene does not degrade in municipal landfills. Of concern to radioactive waste forms, however, is the potential for degradation and hydrogen gas generation as a result of radiation-induced reactions. An evaluation conducted by Rocky Flats concluded that radiolysis effects for low level radioactive (<100 nCi/gram) waste streams encapsulated in polyethylene are insignificant (7). In terms of the mechanical properties, low level waste streams do not have a sufficiently high specific activity to deliver the 100 megarads required to significantly degrade the polyethylene. Hydrogen gas generation is also insignificant with these waste types. Polyethylene extrusion is not a feasible option for high specific activity waste streams due to the potential for radiolysis effects. This is not an issue, however, for low level waste forms.

Another area of concern evaluated by Rocky Flats was the issue of the thermal stability of sodium nitrate waste streams encapsulated in polyethylene (7). Encapsulating sodium nitrate, an oxidizer, with polyethylene, an organic, could potentially result in a chemically reactive mixture. Such a mixture of fuel and oxidizer could burn if exposed to sufficient thermal energy, and consequently release additional energy and gases. Experiments conducted to evaluate the issue of the thermal stability of the sodium nitrate/polyethylene waste form conclusively demonstrated that no exothermal reaction hazards exist. A wide variety of tests have been conducted, including calorimetry, ignition, time-to-explosion, thermal decomposition, gas evolution, detonation, and thermal runaway. None of the experimental results indicate any tendency to detonate or explode, even under wide variations in the waste-to-polyethylene ratio.

Favorable results have been achieved on bench-scale treatability studies and limited cold pilot-scale testing; however, no pilot-scale tests have

been conducted to date on polyethylene micro encapsulation of actual low level mixed wastes. This is critical to demonstrating the technology's performance. Rocky Flats has recently acquired a twin screw extruder for pilot scale testing of large quantities of actual low mixed salts, sludge, and ash. In conjunction with Rust Federal Services, Rocky Flats will be conducting extended hot pilot-scale tests using this extruder in mid-1996. In addition to supporting the pilot-scale tests, Rust will use resources available through its sister company, Waste Management, to investigate the economics of collecting appropriate plastics for mixed waste treatment.

USE OF RECYCLED PLASTICS FOR WASTE ENCAPSULATION

The ideal plastic for mixed waste treatment would be readily available, chemically resistant, and inexpensive. In order to simplify operations and produce an acceptable waste form, the plastic needs to have a low melt viscosity (melt index greater than 50) and cannot contain co-polymers or plasticizers that would offgas at extruder operating temperatures. Rocky Flats has had the most success with low density polyethylene (LDPE) and linear low density polyethylene(LLDPE). High density polyethylene (HDPE) is more widely used by industry, but it is not appropriate for most Rocky Flats applications because large monolithic pours of HDPE tend to shrink and crack upon cooling.

LDPE and LLDPE, with the exception of films containing copolymers or plasticizers, are not currently being recycled in Colorado. Common post-consumer sources of this material are food containers, especially lids. The challenge is to collect sufficient quantities of relatively clean material without burdening the recycle vendor with unwanted plastics. There are several options for accomplishing this.

One option is to add LDPE and LLDPE to current curbside collection programs. In recent years, recycling has become a significant part of waste collection systems throughout the country. "Waste Minimization" programs have increased the awareness of homeowners and corporations of the advantages of recycling. As a result, the addition of another "product" in curbside collection systems would not be extremely difficult. The concern of the recycle vendor is that, because Rocky Flats is the only market for these plastics, too much material will be collected. Targeting specific geographic areas, such as certain neighborhoods, is usually not feasible for large recycling companies. The burden of disposing of additional unwanted plastics significantly reduces the economic viability of this option.

Another option is to sort the desired plastics from the material currently collected through curbside recycling programs. Frequently, consumers inadvertently place LDPE or LLDPE containers in recycling bins specified for HDPE and polyethylene terephalate (PET) only. The recycler must then separate the LDPE, LLDPE, and other unwanted plastics from the HDPE and PET. Currently, plastics other than HDPE and PET are discarded. The recycle vendor can collect sufficient LDPE and LLDPE from the discarded plastics to augment, but not satisfy, Rocky Flats needs. The problem with this option is that processing and transportation of limited quantities of post consumer plastics is not economically viable.

Another option is to collect the required plastics from local companies willing to collect and/or provide waste plastics to Rocky Flats as a public service. One local grocery chain, for example, already provides bins for customers to drop-off recyclable materials. The company would be willing to collect LDPE and LLDPE for Rocky Flats This reduces overall

product costs to Rocky Flats by eliminating collection costs, but processing and transportation costs are still an issue. Processing and transportation of the material includes transportation from the source to a processing plant and from the processing plant to the point of use. Effective processing methods (such as pelletizing to reduce volume) may significantly reduce transportation costs, thereby reducing overall product costs to Rocky Flats.

One large manufacturing company in the region has offered to donate waste plastics to Rocky Flats for use in mixed waste treatment. This is obviously the best option for Rocky Flats, since it eliminates product costs and the volumes can be easily controlled. Unfortunately, the available plastics are not optimum for Rocky Flats applications, although they may be usable. Materials testing still needs to be completed to determine whether the available plastics are suitable for Rocky Flats needs.

If this material is deemed unsuitable to Rocky Flats, then the required plastics may be collected from companies manufacturing products such as food containers or food lids. This material is sold as "regrind" and is typically clean and readily available. It costs significantly less than virgin polyethylenes, but it must be shipped to Colorado from other states. Although Rocky Flats is currently using this material to satisfy existing needs, the preference is to utilize plastics that are being landfilled in Colorado.

CONCLUSIONS

Polymer encapsulation is a good treatment option for many mixed wastes, especially wastes that are difficult to stabilize using cementation or vitrification. Some of the advantages include high waste loading, excellent waste form durability, and insensitivity to variations in waste stream chemistry. Public acceptance of the technology is enhanced because waste plastics can be used to treat wastes.

The appropriate plastics for mixed waste treatment are not currently being recycled in Colorado. While this provides the DOE an opportunity to put to beneficial use materials that would otherwise end up in a municipal landfill, it also presents some challenges. The main challenge is to identify collection, processing, and transportation methods that are economically viable.

Four options for collecting the appropriate waste plastics were presented in this paper. One of the options, collection of "regrind" from companies that manufacture plastic products, is currently used at Rocky Flats. This option costs significantly less than procurement of virgin polyethylenes, but Colorado does not directly benefit since the waste plastics are shipped from other states.

The best overall option is to collect waste plastics from local companies willing to collect and/or provide plastics to Rocky Flats as a public service. This option utilizes plastics that are currently being landfilled in Colorado while reducing (or eliminating) product costs to Rocky Flats.

ABSTRACT

Stabilization is a "Best Demonstrated Available Technology" or "BDAT" as defined by the Environmental Protection Agency (EPA) in Title 40, part 268, of the Code of Federal Regulations (40 CFR 268). This technology traps toxic contaminants (usually both chemically and physically) in a matrix so that they do not leach into the environment. The typical contaminants that are trapped by stabilization are metals (mostly transition metals) that exhibit the characteristic of toxicity as defined by 40 CFR part 261. Pozzolanic materials have been routinely used in stabilization. Portland cement, fly ash-lime mixes, gypsum cements, and clays are some of the most common materials. These materials are used because they are inexpensive, easy to use, and effective for wastes containing low concentrations of toxic materials.

In many instances, passing the Toxicity Characteristic Leaching Procedure, TCLP, (i.e., Federal leach test) or the Soluble Toxicity Leachate Concentration, STLC, (i.e., CA leach test) requires high concentrations of lime or other caustic material because of the nature of the leaching media. Both leaching media, California's and EPA's, have a pH of 5.0. The State uses citric acid and sodium citrate. The EPA uses acetic acid and sodium acetate. These media also can form ligands that provide excellent metal leaching. In several circumstances, due to the aggressive nature of the leaching medium, stabilized wastes will not pass. The concentration in the leachate is approximately 10 times higher for the STLC procedure than the TCLP.

Additives such as dithiocarbamates and thiocarbonates, that are pH insensitive and provide resistance to ligand formation, are used in this stabilization process. Attapulgite, montmorillonite, and sepiolite clays are used because they are forgiving (recipe can be adjusted before the

matrix hardens) when formulating a stabilization matrix and they are neutral in pH.

Passing the TCLP and STLC has been achieved for highly concentrated wastewater treatment sludges by using these clays and additives. The most frequently used stabilization process consists of a customized recipe involving waste sludge, clay and dithiocarbamate salt, mixed with a double planetary mixer into a pasty consistency. TCLP and STLC data on this waste matrix have shown that the process matrix meets land disposal requirements.

INTRODUCTION

Stabilization is considered a Best Demonstrated Available Technology (BDAT) by the Environmental Protection Department and is the technology of choice for passing regulatory leachate tests such as the Toxicity Characteristic Leaching Procedure (TCLP) and the California Assessment Manual Wet Extraction Test for Soluble Toxicity Leachate Concentration (CAM-WET STLC).

The primary purpose for solidification/stabilization technologies for low-level mixed waste is to meet land disposal restrictions under the federal regulations (40 CFR 268).

To assure that the solidification/stabilization technology is acceptable, the processed material must pass the regulatory leach tests. The TCLP extract concentrations and the STLCs are applied to California waste when the waste is disposed at the Nevada Test Site and are applied to waste constituents which are given in the Constituent Concentrations In Waste Extract (CCWE) table (40 CFR 268.41) when the Universal Treatment Standards (40 CFR 268.48) apply. The CAM-WET in California is a much more aggressive test and applies to many more constituents such that frequent customization and verification of success is required.

EPA recognizes that Stabilization is a BDAT. Therefore stabilized wastes do not need to be sampled to verify they meet land disposal restrictions. However it is good practice to verify that the wastes pass STLC and verification is required by the Nevada Test Site for 10% of our wastes. Lawrence Livermore National Laboratory's (LLNL's) current work applies to wastes exhibiting the characteristic for toxicity and bear one or more of the EPA codes D004 through D011. California constituent radioactive wastes must also be treated, as a requirement of the Nevada Test Site, prior to disposal. Treatment of California constituent wastes, that are radioactive also, allows LLNL to develop techniques necessary to meet the universal treatment standards when promulgation requires treatment of underlying constituents for metal characteristic codes.

Currently, mixed wastes that exhibit the characteristics of corrosivity (D002), low total organic carbon (TOC) ignitability (D001), or toxicity for pesticides (D012 through D017) must be treated for all underlying constituents to meet land disposal requirements. Table I summarizes threshold limits for metals, EPA codes, and underlying constituents.

The waste requiring stabilization at LLNL is filter-aid sludge from processing wastewaters generated through various systems within the LLNL Site. This filter-aid sludge does not exhibit the characteristics which require LLNL to treat underlying constituents. However, to dispose of the waste at the Nevada Test Site, the State of California regulations apply which require LLNL to pass the STLC. The metals analyzed in the STLC are the same as the underlying constituents in EPA's Universal Treatment Standard. Table II gives the metals analyzed and the CAM-WET threshold limit for hazardous waste.

The differences between the Federal (TCLP) and the California State (STLC) leaching tests are subtle but provide substantial differences in test results. The differences in these tests for the stabilized wastes are summarized in Table III.

Examination of Table III shows that the California State leaching test is more rigorous in all categories but pH and Extraction Fluid Weight Ratio. The citrate buffer has greater soluble ligand formation properties than does the acetate buffer. Both anions form soluble complexes with metals but, citrate has much larger formation constants and can form bidentates and tridentates with metals in the presence of hydrogen (as in a pH of 5.0). Both buffer strengths are the same for this type of waste. Wastes, that are not pasty, are ground up to a certain particle size. The particle size for the STLC is 5 times smaller than for the TCLP. This provides the STLC with a steeper internal diffusion gradient. The leachate time for STLC is longer so that more contaminants leach out. There is twice as much extraction fluid in the Federal test but this may not be as significant. The more fluid does provide for a larger diffusion driving force but, this is not significant for lower concentrations (parts per million range).

Table I

Table II

Table III

RAW WASTE CHARACTERIZATION

The waste to be stabilized originates as aqueous waste. The metal constituents in the wastes are precipitated predominantly with hydroxide ion. The waste is then filtered through a rotary-drum vacuum-filter to remove the hydroxide precipitate. The rotary-drum vacuum-filter uses diatomaceous earth (filter-aid) to trap the precipitate. This spent sludge is periodically cut from the rotary drum during the aqueous waste treatment process. The filter-aid sludge collected is sent to our processing building for stabilization. The filter-aid sludge contains about 60% water, with the balance of the material being diatomaceous earth, metal contamination, and often organics, such as, oil and carbon. The metal contamination in the sludge varies widely from batch to batch, since the waste streams processed are widely varied. Typically one 5 cubic meter aqueous waste batch will yield one to two 0.2 cubic meter drums of diatomaceous earth waste. A typical example of the filter-aid sludge in a drum that requires stabilization is given in Table IV.

Table IV

The diatomaceous earth waste itself has little resistance against either the Federal or State leaching test. This is to be expected since hydroxide precipitates cannot hold up against any mild acid buffer regardless of its ability to form soluble complexes with metals. Metal hydroxide solubilities can be calculated from first principles using hydroxide formation constants, solubility products, and assuming unity for activity coefficients. Cadmium, lead, and zinc appear to be completely soluble at a pH of 5.

Table IV demonstrates the wide variety of metal constituents found in the filter aid sludge. The highest in the subset shown is nickel at 2076 mg/Kg. Usually the largest concentration of metal contamination in the waste sludge does not exceed 5,000 mg/Kg. The more concentrated sludges at LLNL are from spent plating baths (electro- and electroless plating). The waste from spent plating baths seldom contains arsenic, antimony, and selenium. These metals usually have to be precipitated as anion complex

and ion exchanged prior to filtration because these metals will not hydroxide precipitate. Fortunately, LLNL does not see much of this type of metal contamination.

THE CLAY MATRIX USED IN STABILIZATION

The primary clays used in LLNL's stabilization process are sepiolite, montmorillonite, and attapulgite. These clays have defined alumina or magnesium oxide-silica layers upon hydration. These clays were chosen because LLNL has worked with these materials in the past and these materials have demonstrated effectiveness in stabilization against TCLP. These clays tend not to increase the total volume of waste to the extent that other clays (e.g., Bentonite clay) do.

These clays possess the ability to hydrate and adsorb hazardous constituents. They form thixotropic fluids when hydrated and have minimal compression strength, but are considered solids from a regulatory standpoint (they pass EPA SW846 9095, Paint Filter Liquids Test).

Montmorillonites are impure forms of Al2O34SiO2H2O. The impurities are magnesium, potassium, calcium, titanium, and iron. The clay is an expanding type which forms a smectite when hydrated. The structure consists of an aluminum hydroxide octahedral in between two sheets of silica tetrahedral. The impurities in the structure are what gives this and other clays the ability to hold cations in place or "sorb" them. The metal impurities which replace silica (and in some instances the alumina octahedral) make the clay become deficient in positive charge. This causes the lattice to have a net negative charge and thus have the ability to "sorb" cations. During the formation of the clay, cationic impurities disrupt the clay matrix by replacing the alumina ions. This is most profound when the two aligning tetrahedral (above and below the octahedral) have substituted alumina for other metal oxides. In the case of this clay. the replacement cations have a less positive charge than the alumina. This results in a net negative charge in the clay lattice. The hydration reaction in its simplest view is given below.

Al2O34SiO2H2O + 2H2O 2[SiO2Al(OH3)SiO2]

Attapulgites and Sepiolites have a similar behavior to Montmorillonite except that the structures are different. Attapulgite and Sepiolite are not just alumina sandwiched between silica. They have ribbon-like structure in which alternating twists in the ribbon are silica and metal oxides. The structure is stable and replacement of the metal oxides is less evident than in montmorillonite. This gives less adsorption capacity but does provide a lower expansion upon hydration. The chemical composition of Attapulgite and Sepiolite is given below.

Attapulgite: (Mg)5Si8O20(OH)2(OH2)44H2O

Sepiolite: (Mg)9Si12O30(OH)6(OH2)46H2O

These formula are based on Nagy and Bradley model and are discussed in "The Chemistry of Clay Minerals", Charles E. Weaver, Elsevier, New York, 1975. These clays do contain aluminum as impurity but at a much lower composition than magnesium.

pH INSENSITIVE ADDITIVES

Since pH, complex formation, and diffusion are the primary driving forces for leaching in these two tests (TCLP, STLC), it is important to focus as much as one can on effective limitation to these phenomena. Molecular diffusion, although modeled in many situations and scenarios (sometimes very complexly), is small. Arguably, the diffusion of interest is between two solid phases, a successfully precipitated metal that is physisorbed to an active site, diffusing through a layer of clay. This is orders of

magnitude smaller than solid-liquid phase diffusion. Complex formation between the citrate and metal is relatively small. The formation constants of the bidentates and tridentates are orders of magnitude smaller that most inorganic solubility products. Acetate salt formation is even smaller still. Hydroxide precipitates do not hold up well against these mild acid buffers. The use of pH insensitive additives is required when high concentrations of metals are found in the sludge. There are many marketed precipitating agents under a variety of names. They are usually sold for waste water treatment. The primary non-hydroxide chemicals sold for precipitation are iron and sodium sulfide, thiocarbamate, and thiocarbonate. These chemicals are all relatively pH insensitive but still work better in alkaline solutions. The solubility products of sulfide or sulfur bearing organic salts are all much lower than hydroxides. Care must be taken in using these materials because they are toxic in their own right.

THE MIXING EQUIPMENT

The mixer used in this process is a double planetary open paddle mixer. It is a "change-can" mixing device which uses a standard 55-gallon (0.2 cubic meter) drum as the mixing vessel or change-can. Its power source is a 15 horsepower (11200 Watt) totally enclosed fan cooled (TEFC) motor operating at 1800 revolutions per minute. The motor shaft is connected to a worm that reduces speed by 40:1. The worm gear is attached to a shaft that is itself attached to a flat circular gear. This gear engages two gears attached to each other, floating freely about the center shaft. These two gears each have a shaft attached to an open paddle. The central shaft turns clockwise, spinning the two opposing gears and their paddles counterclockwise. As the two paddles spin counterclockwise about their own axis, they spin together clockwise about the center gear. Thus each paddle behaves as a planet spinning on axis, rotating around the sun (center gear). All three gears are approximately the same size and thus spin at about 45 revolutions per minute. This would appear slow (less than 1 revolution per second) if you did not see three motions occurring at once.

This mixing action is needed because the clay and diatomaceous earth mixture is a thixotropic pseudoplastic. It has extremely high viscosity until a high shear is applied and, it is a free standing monolith when it is not being forced to move. Low speed high shear mixing is more appropriate for this type of material than is high speed low shear mixing.

PROCESS DESCRIPTION

The process has been implemented using water that is already contained in the diatomaceous earth. The amount of stabilizer added was calculated to solidify the water in the sludge, not the entire weight of the sludge. Much of the preliminary product was too soupy due to water additions or due to not knowing how much water was in the sludge. Now, the first step before stabilization begins is a moisture determination. This is performed in a standard laboratory oven at approximately 600C and 600 grams of waste. The average moisture content is about 55% but it varies between 33% and 80% depending on the aqueous waste treated. The amount of clay added to the waste is determined by using the following formula:

$M = (0.6)(X)(Z)$

M = mass of clay to add

X = mass fraction of water in the waste

Z = mass of waste sludge

This formula gives a consistent, stiff matrix. It allows for easy cleaning of the equipment because the clay matrix sticks to itself much more than to the open paddles. It also proves not to readily dehydrate when sealed in a drum to cure.

Additives are used when metal concentrations are too high to just use the clay. In many instances clay alone provides little fixation. Table V shows the original raw material concentrations of metals with the STLC values after stabilization. A fair comparison can be made if one takes the STLC value, multiplies the value by 10 (this is the dilution caused by the citrate buffer), then multiples by the ratio of stabilized net mass to mass balance net mass. As one can see, fixation does not occur in many cases and dilution is the main effect (values for zinc demonstrate this in Table V). Figure 1 shows a good way to present data to demonstrate the fixation of a metal constituent. The total constituent mass is calculated, then the percentage of the amount of metal leached is calculated. A direct comparison of the amount leached in the original waste form and the stabilized waste form can then be made.

Table V

PROCESS ANALYSIS

Figure 1 shows the results of stabilization with clay only. For many metals at moderate concentrations, fixation with clay is adequate to perform the fixation. Cadmium and cobalt show an order of magnitude reduction in leachate concentration upon stabilization with clay only. Nickel shows greater than one order of magnitude reduction and copper shows varying reduction in leachate concentration up to two orders of magnitude.

If the waste sludge contains greater than a few hundred grams of the metals mentioned above or contains metals such as chromium, molybdenum, vanadium, and zinc, additives are required to perform the stabilization successfully. Additives were first added at stoichiometric ratios plus 10% excess. This proved unsuccessful. Often stabilization was not successful unless 100 times stoichiometry was used. Currently, 12% by weight of waste is used and only dithiocarbamate (DTC) has been successful at this concentration.

Fig. 1

LLNL found that the sequence of stabilization is very important and that two mixing stages are needed. First, the pH insensitive precipitating agent is added, the waste sludge and additive are allowed to mix. The mixing continues for two to five minutes. The waste and additive are well mixed at this point and the reprecipitation has occurred. Next the clay is added and mixed. This locks the reprecipitated metals in the media and physisorbs it and any other materials still free in the matrix.

Figure 2 below shows a similar chart for stabilized wastes using dithiocarbamate. In every case except for barium, fixation has occurred. There was essentially no detection of nickel or silver in the leachate of stabilized wastes. This clay and dithiocarbamate showed very low leachate fractions for metals accept for arsenic which does not readily precipitate with DTC and usually exists in anionic form in wastewaters. Nevertheless, some reduction in leaching was observed.

Figure 3 shows the decrease in leachate concentration with the addition of DTC. The decrease is dramatic when the DTC additive is between 3% and 12% by weight of raw waste. These wastes originally had 3200 mg/Kg Nickel, 745 mg/Kg Copper, 429 mg/Kg Zinc. Leachate concentrations for

these wastes after stabilization with clay and dithiocarbamate were less than 1 mg/L; all stabilized wastes passed the TCLP and STLC.
Fig. 2
Fig. 3
CONCLUSION
In many cases the use of clay alone can fix metal constituents in a waste form. In other cases, fixation must be augmented. Using clay alone when metal concentrations are high will not fixate metals enough to pass the STLC. The pH insensitive additives, such as dithiocarbamate or other sulfide bearing compounds, may need to be used. Without the use of pH insensitive additives, metal salts become available to the leaching fluid because the interaction of the clay and the metal hydroxide is weak. With the salts available and at a pH of 5.0, metal hydroxide dissolves into the bulk extractant in the form of citrate or acetate salts and salt complexes. The addition of DTC at concentrations between 6 and 12% of the raw waste precipitate metals so that the clay matrix passes the STLC.

Richard Kimmel
U.S. Department of Energy
Idaho Operations Office
ABSTRACT
According to the data developed for the Proposed Site Treatment Plans, the U.S.Department of Energy (DOE) mixed low-level and mixed transuranic waste inventory was estimated at 230,000m3 and embodied in approximately 2,000 waste streams. Many of these streams are unique and may require new technologies to facilitate compliance with Resource Conservation and Recovery Act disposal requirements. Because most waste streams are unique, a demonstration of the selected technologies is justified. Evaluation of commercially available or innovative technologies in a treatability study is a cost-effective method of providing a demonstration of the technology and supporting decisions on technology selection.
This paper summarizes a document being prepared by the Mixed Waste Focus Area of the DOE Office of Science and Technology (EM-50). The document will provide DOE waste managers with a list of commercial firms (and universities) that have mixed-waste treatability study capabilities and with the specifics regarding the technologies available at those facilities. In addition, the document will provide a short summary of key points of the relevant regulations affecting treatability studies and will compile recommendations for successfully conducting an off-site treatability study.
Interim results of the supplier survey are tabulated in this paper. The tabulation demonstrates that treatment technologies in 17 of the U.S. Environmental Protection Agency's technology categories are available at

commercial facilities. These technologies include straightforward application of standard technologies, such as pyrolysis, as well as proprietary technologies developed specifically for mixed waste. The paper also discusses the key points of the management of commercial mixed-waste treatability studies.

INTRODUCTION

Treatability studies represent a ready vehicle for U.S.Department of Energy (DOE) waste managers to evaluate and demonstrate both available and innovative treatment technologies on mixed-waste streams. The U.S.Environmental Protection Agency's (EPA) Resource Conservation and Recovery Act (RCRA) regulations (Title 40, Code of Federal Regulations, Part 261 and following) exempt limited volumes of waste from treatment in fully permitted facilities for the purposes of technology screening and process data compilation. In most states, up to 1,000 kg of hazardous waste and up to 10,000 kg of media contaminated with hazardous waste can be treated under the RCRA treatability study exemption. The Toxic Substances Control Act (TSCA) regulations are less specific on this point but recognize the need.

COMMERCIAL MIXED-WASTE TREATABILITY STUDY SUPPLIERS

To provide a service to DOE's waste managers, the Mixed Waste Focus Area (MWFA) of the DOE Office of Science and Technology (EM-50) is undertaking a survey to identify firms with current capability in the treatment of mixed waste at the treatability study scale. The survey has compiled candidate firms from three sources of information. The EPA's Vendor Information System for Innovative Treatment Technologies (VISITT) database was queried for firms with a background in the treatment of both hazardous and radioactive waste. The DOE Tech-Con database, resident at Argonne National Laboratory, was also reviewed. Finally, Lockheed Martin Idaho Technologies published an announcement in the Commerce Business Daily to identify any new sources.

Over 100 firms were identified from these three sources, and a representative from the MWFA contacted all firms by phone to determine whether they have current capability and interest in participating in the survey. Subsequently, the interested firms were sent questionnaires to characterize their capability and history in mixed-waste treatability studies. Contact information of some firms was not correct, and those leads were deleted from further consideration. To identify and confirm each firm's specific capability, the questionnaire asked for the following:

- Name of facility and facility contact
- Technologies available through that firm
- Waste matrices/hazardous constituents treated by that firm
- Copies of radioactive material licenses (to identify curie limits in acceptance)
- Relevant other limits of their waste acceptance criteria
- Demonstration unit capacity
- Treatability study history
- Lists of publications or technical papers presented on the results of that firm's treatability studies.

Information from the survey forms has been received, and pertinent information has been compiled into a database. At this time, the survey results are considered "work in progress," as a number of firms failed to respond and some responses raise questions. In addition, the MWFA intends

to categorize the companies into several groups after detailed review of the questionnaires.

Table I presents the information received (to date) according to the general treatment technology category available from the firms. It also lists the firms in each technology category along with their contact names and phone numbers. This table was compiled directly from the questionnaire results with limited validation.

Table Ia

Table Ib

Table Ic

Table Id

Table Ie

DOE facilities interested in complete questionnaire responses should contact the MWFA at the Idaho National Engineering Laboratory in Idaho Falls, Idaho.

The following conclusions result from the data presented:

Eighty-two processes are available in 17 of the EPA's general technology categories.

Responses have included both waste management and environmental restoration technologies.

At least three different categories of firms responded to the questionnaire. A limited number have current capability for mixed-waste treatability studies in existing processing systems with U.S. Nuclear Regulatory Commission (NRC) (or state) permits for radioactive materials and have either treatability study capability or full RCRA operating permits. A second group of respondents has technologies available, but mixed-waste treatability studies are available at permitted facilities owned by others. A third group identified technologies but made no indication of mixed-waste treatability study capability.

Several firms expect an NRC or state radioactive materials license very soon.

Many firms responded positively to the telephone screen but did not return the completed questionnaire.

Radioactive license limits are typically radionuclide-specific, but total curie possession as high as 10 is available.

Two commercial suppliers identified the ability to accept plutonium in gram quantities.

Prior to issuance of the report from the MWFA, several additional checks will be made. Data will be presented to identify the firms by category: those with fully permitted facilities, those with a technology and access to fully permitted facilities, and those with a technology only. Note that the MWFA requested copies of relevant permits and licenses. This information will be used to confirm capabilities, where appropriate. In addition, each firm will have an opportunity to correct or expand on information presented. After these data checks, the supplier data are expected to be considered complete for publishing.

TREATABILITY STUDY MANAGEMENT ISSUES

The MWFA document also provides recommendations for conducting mixed-waste treatability studies. This information was compiled from several EPA guidance manuals and discussions with DOE waste managers who have contracted for off-site treatability studies as well as from reports generated within DOE. The document discusses the issues in detail. The following are some key points taken from the discussion:

The document generally advises that each of DOE's waste streams is in some fashion unique, and a quick confirmation of the applicability of a technology is excellent insurance against process failure.

Several of the EPA guidance documents (1, 2, 3, 4, 5) address the development of the overall project objectives. Generally speaking, the level of data quality should be adjusted to reflect whether the treatability study is a simple screening test or one that is performed to develop complete process design data.

The availability of commercial suppliers of a technology and treatability study can significantly affect cost. In particular, the availability of an existing pilot plant can offer a significant cost and schedule advantage.

Residues disposition should be carefully considered. Generally, the residues from a treatability study are subjected to a hazardous waste determination, and it is important that the original generator not be required to perform additional treatment on the residues.

Jolley et al. (6) recommends a readiness review to ensure that all contractual, regulatory, and health and safety issues be considered prior to conducting the test.

At least one run of a treatability study should be observed to ensure compliance with the test plan.

A management process for approving quick changes in the treatability study should be implemented. Frequently, project changes may be warranted based on interim results, and a rapid change approval expedites the treatability study completion.

TREATABILITY STUDY REGULATORY FRAMEWORK

DOE mixed-waste treatability studies, conducted in accordance with the RCRA, are potentially subject to numerous other national and state regulations, as well as to various DOE Orders. Treatability studies dealing with environmental restoration wastes generated at sites regulated under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) will be subject to CERCLA requirements. If the treatability study involves polychlorinated biphenyls, the requirements of the TSCA will apply. If the study is conducted at a commercial treatability study laboratory or treatment facility, the facility must have a received radioactive materials license from the NRC. Waste samples transported to off-site facilities by common carriers must meet packaging requirements of RCRA, the NRC, and the U.S. Department of Transportation. DOE Orders on the management of a commercial facility will also apply. The DOE is also responsible for complying with the provisions of the National Environmental Policy Act.

The MWFA document will discuss each of these regulatory frameworks separately and will summarize pertinent issues to be addressed.

CONCLUSION

Treatability studies represent a viable option for demonstrating available and innovative technologies on DOE mixed wastes. The MWFA will continue to collect information from treatability study firms, analyze the data, and verify capabilities before publishing the results. Interim results from the survey indicate that there are a number of commercial and university suppliers who can currently demonstrate technologies in their own licensed facilities, and there are many other technology owners with access to facilities with the appropriate permits and licenses.

ABSTRACT

Preliminary treatability studies were performed during fiscal year 1995 (FY95) at Brookhaven National Laboratory (BNL) for polyethylene encapsulation of low-level mixed wastes from Idaho National Engineering Laboratory (INEL). Treatability work included thermal screening and/or processibility testing to determine the applicability of polyethylene encapsulation for solidification of priority wastes identified by INEL. Seven candidate wastes were selected and investigated during this study. However, for purposes of this paper and to provide a thorough review of the experimental method, processing results will only be presented for the highest priority INEL waste; Eutectic Salts (INEL ID#SMC-507). Thermal screening was conducted by Differential Scanning Calorimetry for this waste to assess the thermal stability under pretreatment and polyethylene processing conditions. Processibility testing to determine whether the waste is amenable to extrusion processing included monitoring feed consistency, extruder output consistency, waste product homogeneity, and waste form performance. A nominal waste loading was selected and successfully processed for a eutectic salt surrogate as well as an actual eutectic salt mixed waste sample. Both surrogate and mixed waste sample waste forms showed marked improvement in lead leachability during Toxicity Characteristic Leach Procedure (TCLP) testing and were below

levels specified by the Environmental Protection Agency (EPA) under the Resource Conservation and Recovery Act (RCRA).

INTRODUCTION

Treatability studies for polyethylene encapsulation of Idaho National Engineering Laboratory (INEL) low-level mixed wastes were conducted at the Brookhaven National Laboratory (BNL) Environmental & Waste Technology Center.(1) The Technical Programs Unit, part of the Waste Management Division of Lockheed Idaho Technologies Company (LITCO), is investigating the use of polyethylene for waste encapsulation in an effort to develop mixed waste treatment alternatives. BNL has developed the extrusion-based polyethylene encapsulation process as an effective waste solidification technology and has demonstrated applicability to a wide range of hazardous, low-level radioactive and mixed wastes.

Treatability work was performed on seven INEL identified priority candidate wastes and included thermal screening and/or processibility testing. The processing results will be presented in this paper only for the highest priority INEL waste stream so that a thorough review of the process and the experimental method may be given. The seven wastes, generated during ongoing processing and maintenance operations or one-time cleanup operations, have been physically and chemically characterized at INEL. Based on the characterization data, surrogates were prepared for each waste stream that closely resembled the actual wastes in chemical and physical form. For three waste streams, including the one discussed in this paper, actual mixed waste samples were processed for confirmation and proof of technique.

The candidate wastes are classified as mixed wastes due to the presence of radionuclides and heavy metals or organics. The seven candidate wastes in order of priority are shown in Table I. The order of priority for this list was determined based on the volume of the waste and the currently available treatment options for each waste. The top three wastes are generated by ongoing activities and therefore are the highest priority. Of these, ion exchange resins and activated carbon may be treated at the INEL Waste Experimental Reduction Facility (WERF) mixed waste incinerator, but treatment alternatives for the eutectic salt waste stream are more limited.

Treatability work for each waste involved thermal screening by Thermal Gravimetric Analysis (TGA) or Differential Scanning Calorimetry (DSC) and processibility testing including any required waste pretreatment. Thermal screening was used to identify wastes containing compounds that may be volatile at either the thermal pretreatment or extrusion processing conditions (120-150C), or to identify wastes that may undergo a phase transition at thermal processing conditions. A surrogate was used during thermal screening testing. Processibility testing to determine whether the waste is amenable to extrusion processing included monitoring material feed, processing consistency, waste product homogeneity and waste form performance. A nominal waste loading was selected and processed successfully for a eutectic salt surrogate as well as an actual eutectic salt mixed waste sample. Processing parameters were not optimized within the scope of this study since the primary focus of this preliminary effort was to simply establish whether these wastes were amenable to polyethylene encapsulation.

Table I

BACKGROUND

Waste Description

Treatability work was conducted on a surrogate of the eutectic salt waste and on a sample of the actual INEL priority mixed waste. This waste stream is also known as Carbonate Eutectic Salt or more recently as Cartecsal. The waste description as provided by INEL is shown in Table II. It is a lead (Pb) contaminated salt mixture roughly comprised of 60 weight percent potassium carbonate, 30 weight percent lithium carbonate, and 10 weight percent sodium carbonate. Characterization conducted at INEL indicated that the salt mixture was a fine powder with TCLP analysis indicating a lead concentration between 4.8-5.8 mg/l. There are currently approximately 29 drums of this waste being stored at INEL.

Table II

Polyethylene Encapsulation Process Description

Polyethylene is an inert, low permeability, thermoplastic material that is highly resistant to chemical attack, microbial degradation and radiation damage.(2) The polyethylene micro-encapsulation process selected for eutectic salts is a solidification technology utilizing polyethylene to solidify waste particles within a polymer matrix. This is accomplished by heating polyethylene above its melting point (120-150C), then mixing the molten polyethylene with the waste. Solidification of the encapsulated matrix is assured upon cooling and is independent of the chemical nature of the waste materials. The BNL polyethylene encapsulation process uses a versatile, industry-tested single-screw plastics extruder. A schematic of the microencapsulation process is shown in Fig. 1. Dry waste and polyethylene are continuously fed to the extruder by individual dynamic feeders and accurately metered to maintain a constant waste loading. The feeders are either volumetric, designed to meter a constant volume of material at a given speed setting, or volumetric feeders retrofitted to a computer-controlled loss-in-weight system. Within the extruder, a variable speed screw mixes the molten polyethylene with the waste material and pumps the homogeneous mixture through a die directly into a waste container. The processing temperature is controlled through five independent extruder zones and a separate die zone. For optimization, the temperature profile can be tailored for different polymer and waste combinations.

Pretreatment is often required of wastes to make them amenable to extrusion processing with polyethylene. The degree of pretreatment is specified by the chemical and physical characteristics of the untreated waste. For successful microencapsulation and to achieve optimum mixing and product/processing consistency, wastes should be dry (less than 2% moisture) and have a nominal particle size distribution of 50-2000 mm. The particle size range may exceed these limits but successful processibility is dependent on the material feeders, extruder and type of screw(s) employed, extruder die configuration, and waste product performance considerations (e.g., leachability). Larger particles that may be processed from an engineering standpoint can reduce the effectiveness of microencapsulation which relies on the coating of individual waste particles. Thus, for any given waste, the larger the particle size, the greater the surface area of unencapsulated waste, and the greater the potential for leaching.

Fig. 1

TREATABILITY STUDY

Surrogate Preparation

The eutectic salt surrogate was prepared according to the composition data provided by INEL. As mentioned, the waste is primarily comprised of

the salts potassium carbonate, lithium carbonate and sodium carbonate. Potassium and sodium carbonate are available as hydrated compounds. Potassium carbonate can be in an anhydrous or sesquihydrate (K2CO31H2O) form. Sodium carbonate can be anhydrous or monohydrate (Na2CO3H2O). Lithium carbonate (Li2CO3) does not complex with water. The compound form of the salts in the actual eutectic salt mixed waste is not known. For thermal screening, the surrogate was prepared without lead using reagent grade hydrated salts. Technical grade anhydrous carbonate salts were used for surrogate preparation for processibility confirmation testing. For treatability testing, the surrogates were spiked with lead at a concentration prescribed by the INEL characterization data, as shown in Table II, that indicted a maximum lead concentration of 5.8 mg/l from TCLP results. Accounting for a 20:1 dilution, a TCLP concentration of 5.8 mg/l is equivalent to 116 ppm in the waste. Thus, the surrogate was spiked with 120 ppm lead in the form of lead chloride.

Thermal Screening

Thermal screening of the eutectic salt surrogate was conducted using a Shimadzu DSC-50 Differential Scanning Calorimeter to determine if waters of hydrations would evolve from the salts at the thermal processing conditions expected during polyethylene encapsulation (120-150C). For DSC analysis, samples weighing approximately 20 mg were heated in the presence of nitrogen from ambient to 150C at 3C/min and held for 40 minutes. A slow heating rate (1-5C/min) is suggested by the manufacturer for observing phase changes due to free or bound water evolution. Each individual carbonate salt and the homogeneous mixture were tested under these conditions. The DSC results, plots of energy (mW) versus time (min), revealed endothermic peaks representing the evolution of bound water for potassium carbonate sesquihydrate and sodium carbonate monohydrate. Figure 2 is a DSC plot that clearly shows the evolution of the water of hydration from sodium carbonate monohydrate. The heating profile can also be discerned on this plot. Similar plots were obtained for potassium carbonate sesquihydrate and the eutectic salt surrogate. The eutectic salt surrogate showed an endothermic peak since it is comprised of the hydrated potassium and sodium carbonate salts. However, lithium carbonate (nonhydrous) did not reveal any phase change for the same heating profile, as expected.

To support and verify DSC results as well as determine the moisture content of the salts, three replicate samples of the eutectic salt surrogate were dried using a Sartorius Moisture Analyzer. Each test was conducted for 30 minutes at 150C. This is the extreme temperature that would be encountered during encapsulation processing and is longer than the approximate 10 minutes residence time in an extruder barrel that the waste would be exposed to during processing. A mass/mole balance was performed in order to determine if the weight loss corresponded to the quantity of bound water in the surrogate containing the hydrated salts. The mean weight loss from the three replicate samples of the eutectic salt surrogate was 11.6 0.27 percent. On a molar basis, hydrated water represents 16.4 weight percent of the compound potassium carbonate sesquihydrate (K2CO31H2O) and 14.5 weight percent of the compound sodium carbonate monohydrate (Na2CO3H2O). The weight percent of water in the eutectic salt surrogate is calculated by multiplying these percent numbers by their respective composition percents in the surrogate (i.e., 0.6 * 16.4 + 0.10 * 14.5) and is equal to 11.3 percent. This number is in close agreement with the weight loss observed on the moisture analyzer.

Based on these results in conjunction with the DSC results, it can be assumed that if the salts comprising the actual eutectic salt mixed waste are hydrated, all waters of hydration will evolve at the temperature required for extrusion processing. Therefore, pretreatment of the waste by drying should be performed prior to extrusion processing.
Fig. 2
Processibility
Processibility testing of the non-radioactive eutectic salt waste surrogate was conducted using a vented, 38 mm (1.5 in.) single-screw extruder. The vent port used along with a carbon trap and vacuum pump removed any volatiles (e.g., moisture) that may have evolved during processing. The INEL mixed waste eutectic salt was processed using a 32 mm (1.25 in.) single-screw extruder contained in an enclosed HEPA filtered process facility. Feeding of the mixed wastes was accomplished through dry material volumetric feeders, and through volumetric feeders retrofitted to a loss-in-weight computer controlled system for the waste surrogates. The standard volumetric feeders were calibrated with the eutectic salt mixed waste and with low-density polyethylene pellets (Chevron 1409). Calibration curves were generated by recording the feeder output (in weight) at different feeder screw speed settings (percent of full speed). Five replicates were taken at a minimum of three separate feeder speed settings. The loss-in-weight feed system consisted of a master feed controller and two slave controllers (one for waste and one for polyethylene). Feeding was accomplished by simply entering the desired total feed rate as well as a recipe for the waste loading (percentage of waste compared to percentage of polyethylene) into the computer controllers.
Extrusion processing for the surrogate and for the mixed waste sample was conducted at a waste loading of 50 weight percent and at a screw speed of 25 rpm. These are not optimized nor maximum processing parameters but rather a conservative starting point that, based on previous experience with waste with similar physical properties, can be readily achieved. Processibility testing with the surrogate included fabricating right cylindrical specimens for compressive strength testing, taking periodic grab samples for density analysis (to monitor waste product homogeneity), and timed one minute samples for processing consistency. Ten replicates were made of each sample for statistical analysis. The densities of the grab samples were determined by weighing each grab sample and using a multipycnometer to determine their volumes. Right cylindrical pellets with a maximum dimension of nine millimeters were also formulated with the lead-spiked surrogate to monitor lead leachability from waste forms by TCLP testing. Processibility testing with the actual eutectic salt mixed waste was limited to confirmation processing while fabricating waste form pellets for TCLP testing. Nearly all of the mixed waste sample received from INEL was used for this task.
Processing of the eutectic salt surrogate was successful. Table III summarizes the extruder output rate and is representative of the processing consistency. The mean output rate at a screw speed of 25 rpm was 77.30 2.00 g/min (95% confidence interval). The small percent error of 2.58% is an excellent reflection on how well the material processed. Generally, materials that vary in output rate as much as 15-20% can still be successfully processed. Feeding and metering of the eutectic salt surrogate was also smooth and consistent. The waste form densities which were calculated from the grab samples taken during processibility testing

are shown in Table IV. The mean density for waste forms containing 50 wt% eutectic salt surrogate was 1.35 0.01 g/cm3. The small density deviations between replicate samples and the low 1.1% error are an indication of the high degree of homogeneity in the waste product.
Table III
Table IV
Waste Form Performance
Eutectic salt waste form specimens were compression tested in accordance with ASTM D-695, "Compressive Properties of Rigid Plastics."(3) The waste form specimens, nominal 5.1 cm (2 in.) by 10.2 cm (4 in.) right cylinders, were turned on a lathe to ensure flat surfaces on the top and bottom then compressed at a constant loading rate of 1.0 0.5 mm/min until the waste form failed or the load within the samples no longer increased with continued loading. The recorded compressive strengths for the ten replicates are shown in Table V. The maximum compressive strength of the waste forms averaged 1.56x104 248 kPa (2260 36 psi). The maximum compressive strength for these waste forms is similar to other polyethylene final waste forms and is well above the NRC waste form compressive strength requirement of 414 kPa (60 psi).
Table V
The leachability of lead from eutectic salt surrogate and actual mixed waste eutectic salt waste forms was conducted in accordance with 40 CFR 261--Identification and Listing of Hazardous Wastes, Appendix II--Toxicity Characteristic Leaching Procedure.(4) The TCLP is an 18 hour extraction of 100 g of sample in 2000 g of a buffered leachant. The leachant or extraction fluid is selected based on a pre-test which determines the pH and the buffering capacity of the sample. An extraction fluid with a pH of 2.88 is used for samples with good buffering capacity and pHs above five otherwise an extraction fluid with a pH of 4.93 is used. Test samples are agitated in an end-over-end fashion for 30 2 rpm for the test duration. On completion, the solutions are filtered into approximately 100 ml aliquots using a 0.6-0.8 micron glass fiber filter. During this study, the concentration of lead in the aliquots was determined by Inductively Coupled Plasma Spectroscopy (ICP) for the nonradioactive surrogate (spiked with 120 ppm lead) and by Hach UV-Spectroscopy for the mixed waste sample. For both TCLP tests, encapsulated waste forms were compared with the untreated samples which served as baselines.
TCLP results are summarized in Table VI. All tested samples were within the RCRA limit of 5 mg/l for lead concentration. The concentration of lead in the encapsulated surrogate (spiked with 120 ppm lead) leachate was undetectable based on two replicate ICP Spectroscopy analyses, compared with concentrations of 4.1 and 4.2 mg/l for the untreated surrogate. The detection limit of the ICP Spectrometer for lead is 0.14 mg/l. A marked improvement in leachability was also seen in samples of the encapsulated eutectic salt mixed waste. Based on HACH UV-Spectroscopy, the baseline or untreated mixed waste sample leached to a lead concentration of 4.1 mg/l compared to 1.8 mg/l for the encapsulated mixed waste samples. Although the current maximum allowable TCLP concentration for lead is 5.0 mg/l, the EPA has recently proposed reducing the allowable concentrations for most Toxicity Characteristic (TC) metals. The new proposed standard for lead is 0.37 mg/l. The polyethylene encapsulated surrogate would pass these new limits but the encapsulated mixed waste sample with a value of 1.8 mg/l would be above

the proposed acceptable limit. To meet the new lower limit, process optimization would need to be performed as well as possibly adding chemical stabilizers during solidification.

Table VI

CONCLUSIONS

Processing of the eutectic salts was successful. This waste is amenable to stabilization by polyethylene microencapsulation. Due to the limited scope of this study, processing parameters were not optimized. At a waste loading of 50 weight percent the leachability of encapsulated waste forms was effectively reduced below current RCRA limits. Higher waste loadings should be achievable from a processing standpoint and based on the successful waste form testing results achieved to date. Thermal screening showed that potassium and sodium carbonate may contain waters of hydration that would require pretreatment drying to prevent volatilization during extrusion processing. Additional processibility work on this waste stream would enable optimization of processing variables and maximize waste loading potential.

ABSTRACT

The 1992 Oak Ridge Reservation FFCA listed a number of mixed wastes, subject to LDR, for which no treatment method had been identified, and required DOE to develop strategies for treatment and ultimate disposal of those wastes. Thermal Desorption and soil washing are two emerging commercial technologies that have typically been used for removing

hazardous organics and heavy metals from contaminated soils, sediments and sludges that are similar to many of these wastes.

This paper presents the results of a program to demonstrate that these technologies can remove both organics, uranium and mercury from a mixed waste from the DOE Y-12 facility in Oak Ridge. TN. This mixed waste sediment from the plant storm sewer system contained mercury, uranium and PCBs. Leachable mercury exceeded TCLP and LDR criteria. This program included bench- and pilot-scale testing of thermal desorption technology. This study also included testing of a soil washing process using physical separation and carbonate extraction to remove uranium. The pilot-scale testing was supported by DOE and EPA through the SITE Emerging Technology Program.

Results of the bench-scale testing of the thermal desorption technology showed that total mercury could be reduced to 120 ppm by treatment at 600oC, which is at the high end of the temperature range for typical thermal desorption systems. Leachable (TCLP) mercury was less than 50 ppb and PCBs were below 2 ppm. Mercury removal in the pilot-scale thermal desorption system was not as high, most likely due to kinetic effects of mercury oxide compound decomposition or inadequate flow of purge gas in the thermal desorber tube. Treated soil from the pilot test did pass TCLP for mercury. The pilot-scale thermal desorption treatment was effective in removing PCBs. The testing also provided information on the characteristics and quantities of residuals from the thermal desorption process. The soil washing process resulted in removal of roughly 50% of the uranium from the sediments and the carbonate extraction was only marginally effective, indicating that the thermal treatment converted uranyl compounds to less soluble species. This program demonstrated that thermal desorption was an effective technology for treating this material to meet waste acceptance criteria for ultimate disposal at a commercial facility.

INTRODUCTION

This project included both bench and pilot-scale testing of the following technologies; thermal desorption, soil washing using physical separation, and chelant extraction. While bench scale testing required less than 10 kilograms of soil, almost 1,000 kilograms were used for the pilot-scale work. The soil for these tests was obtained from the Department of Energy's Y-12 facility, located in Oak Ridge, TN. and operated by Martin Marietta Corporation. This material contained hazardous organics, heavy metals, and radionuclides.

The primary goal of the bench scale tests was to identify optimum operating conditions and performance for the various treatment technologies. The pilot scale tests then provided additional performance and scale-up data needed for evaluation of the potential for full scale application of these technologies. This paper presents the results of these studies.

Waste Characteristics

The Y-12 Storm Sewer Sediment waste was generated during a clean-up and upgrade of the storm sewer system of the DOE Y-12 facility in Oak Ridge, Tennessee. It consisted of sand and silt that had collected in the plant storm sewer lines and contained hazardous organics, heavy metals, and radionuclides. IT received four 55-gallon drums of the waste at the IT Environmental Technology Development Center in Oak Ridge, TN. The material was mixed and homogenized before analysis and testing. Average mercury content in the storm sewer sediment was 22,750 mg/kg. Total

activity of the sample was 9,000 pico-curies per gram for total uranium. The initial PCB concentration of the sample was 149 mg/kg.

Treatability Study Objectives

The primary purpose of the treatability study was to demonstrate that the thermal desorption and soil washing process could meet the performance requirements for removal/reduction of PCBs and mercury from the storm sewer sediments. The performance requirements or treatment criteria for the waste were 12 mg/kg total mercury, 2 mg/kg PCBs and 0.2 mg/liter leachable mercury, as measured by the TCLP. The 12 mg/kg treatment standard for total mercury was a risk based level for disposal in an on-site landfill. Alternate treatment criteria, based on disposal at an off-site permitted radioactive mixed waste facility, required that the material meet the LDR total mercury limit of 260 mg/kg and also meet the TCLP and 2 mg/kg PCB limits.

A secondary treatment objective was to remove the uranium from the sediments so that they could be managed as a non-radioactive material. This study was also designed to generate limited data on the fate of the mercury, PCBs and uranium during thermal treatment and on other contaminants in the residuals from the off-gas treatment system.

BENCH-SCALE THERMAL DESORPTION TESTING

Bench-scale thermal tests were performed to confirm the effect of primary treatment variables (time and temperature) on the reduction of mercury and hazardous organics. The tests also enabled an assessment of the characteristics of the residuals collected from the off-gas, an important factor for the preparation of the pilot tests. The bench thermal treatment program included screening tests in the tube furnace apparatus and tests in the rotary thermal apparatus (RTA).

The tube furnace tests were conducted in a 1-inch diameter by 16-inch quartz tube placed in an electric furnace. The purge gas was treated with a chilled condenser and sulfur impregnated carbon. Three different purge gases (air, nitrogen, and steam) were tested for mercury removal. Based on IT's previous experience, two separate treatment temperatures of 450C and 550C were selected with treatment times of 10, 15, and 20 minutes. Additional screening tests were conducted using the tray test apparatus and a muffle furnace. These tests were conducted to rapidly screen an expanded range of treatment conditions. Based on the results of the tube furnace analysis, temperatures of 550C, 600C, 650C, and 700C were tested at a treatment time of 10 minutes. In addition to these tests, treatment times of 10, 20, 40, 60, and 90 minutes were tested at a 550C temperature.

The results of the tube tests show that the total mercury concentrations were readily reduced to 50 to 100 mg/kg. These results also show that different atmospheres (the three different purge gases) had no significant effect on the mercury levels in the treated soil. The TCLP analyses show leachable mercury was reduced to below 0.011 mg/Liter. In the system's purge gas condenser, elemental mercury was collected. As for the organics, PCB concentrations were typically below 1 mg/kg. These results met the LDR criteria of 260 mg/kg total mercury, but not the risk based level of 12 mg/kg necessary for an on-site landfill.

A series of tray tests at higher temperatures and known treatment times were conducted in order to try and meet the 12 mg/kg total mercury criteria. The treated soil from the tray tests contains concentrations of total mercury between 70 and 115 mg/kg. The more aggressive treatment conditions did not consistently result in lower mercury levels. As the

test temperature was increased, the mercury concentrations were reduced in the treated soil. The test at the highest temperature (700C, 10 minutes RT) did produce the lowest mercury number at 72 mg/kg. However, the results of the varying treatment times were not consistent. The longer contact times at temperature did not provide any significant benefit.

The third phase of the bench, thermal treatment program was the RTA analysis. The RTA is a bench-scale system, basically a small, batch kiln, capable of treating up to 1 kg of soil. The RTA provides scaleable data for the pilot test conditions. The off-gas was treated by chilled impinger scrubbers and sulfur impregnated carbon. Two duplicate runs were conducted at two sets of treatment conditions. The first set of conditions required a temperature of 600C, with a time of 10 minutes at temperature, and an air purge at a rate 1.8 liters per minute. The second set of conditions had a temperature of 350C, with a time of 10 minutes at temperature, and a steam purge at a rate 3.0 liters per minute.

The first set of conditions (600C, 10 minutes RT, air purge) reduced the PCBs and leachable (TCLP) mercury levels to below detection limits. The total mercury concentrations of the treated soil were 141 and 82 mg/kg for the duplicate runs. The second set of conditions (350C, 10 minutes RT, steam purge) resulted in residual PCB concentrations of 2.5 and 3.2 mg/kg for the duplicate runs. The total mercury in the treated soil was 3700 and 4100 mg/kg, but the leachable mercury was below the detection limit of 0.002 mg/liter.

PILOT-SCALE THERMAL DESORPTION TESTING PROGRAM

After the bench-scale desorption test results had been evaluated, approximately 1000 lbs. of contaminated soil were thermally treated at 600C with a 10 minute retention time. The primary goal for the pilot-scale operations was to provide performance and scale-up data for full scale application and to provide sufficient material for soil washing and water treatment studies

Pilot System Description

IT's pilot-scale thermal desorber is an indirectly heated, rotary tube calciner (desorber) unit employing a continuous feed and a multistage off-gas treatment system. The pilot system has in past studies given comparable results to bench-scale tests. The thermal desorber is a pilot calciner that consists of a continuously rotating tube partially enclosed with a gas-fired furnace shell. The tube, constructed of Castalloy H-H, has a 16.5-cm (6 and 1/2-inch) internal diameter and is 4.3 m (14 feet) long; the heated section is 2.3 m (6 feet, 8 inches) long. Small flights are placed at intervals within this tube to provide soil agitation. A stationary thermowell extends from the discharge end into the tube with six thermocouples to monitor the soil temperature and three to monitor the gas temperature along the tube length. The tube can be rotated at speeds from 1.5 to 16 rpm and also can be inclined to adjust the flow rate of solids. Typically, a 2- to 3-degree slope is used.

The soil bed volume in the desorber depends on the material flow characteristics, the desorber inclination and rotational speed, and, particularly on the diameter of the "dam" or retaining ring at the discharge end. The soil residence time is a function of the soil bed volume and the soil feed rate. The soil feed rate is controlled by the rotational speed of a feed screw conveyor. Retention time tests were conducted to determine the slope and rotational speed of the desorber tube required to promote flow of the soil through the tube at the feed

rate. Solids discharging from the separator while operating at steady-state are weighed on a digital electronic scale to enable determination of the soil feed rate.

The furnace is a refractory-lined chamber with 14 equally spaced burners controlled by a standard burner control system with appropriate safety features. Propane was used as the fuel. Burner firing rate is manually controlled to give the desired soil temperature profile. The desorber is rated at 337,000 kilojoules per hour (kJ/hr) (320,000 British thermal units per hour [Btu/hr]) maximum heat duty. The maximum heat that can be transferred to material in the desorber tube is estimated to be 105,000 kJ/hr (100,000 Btu/hr). This value depends primarily on the temperature gradient between the soil being processed and the furnace temperature. The discharge end section of the desorber tube is enclosed by the air cooler casing. Cooling of solids within the tube at the discharge end is increased by forced air circulation through the air cooler casing. Soil exits the desorber tube through a gas plenum/transition section and a rotary air-lock valve into a metal receiver can. A sight glass on the discharge plenum of the desorber allows the soil flow to be visually monitored.

Purge gas is introduced at a low flow rate (0.057 cubic meters per minute [m3/min] [2 actual cubic feet per minute, at the soil discharge end to help flush desorbed contaminant vapors and to maintain the proper atmosphere for the treatment process. The off-gas which flows from a plenum at the soil feed end of the desorber containing the purge gas, volatilized contaminants and water, and some particulates, was transferred through a short electrically-heated, insulated duct to the off-gas treatment system.

The off-gas treatment system was comprised of the following components:

A hot cyclone removes a majority of entrained particulates

A quench, spray scrubber is 15.4 cm (6 inches) in diameter and 1.2 m (4 feet) tall. A demister pad is located at the top of the scrubber to minimize entrainment of water droplets. The scrubber liquid is collected in a tank and recirculated by a pump through a set of bag filters and through a heat exchanger cooled by a packaged refrigeration system. Caustic is added to the scrubber liquid prior to operation to control/maintain the pH to alkaline or neutral.

A wet electrostatic precipitator (WESP) captures very fine particulates and aerosols.

A chilled, noncontact condenser reduces the moisture content of the scrubbed gas and removes condensable organic vapors. The condensate is collected in a receiver.

A mist eliminator (Brinks) removes any remaining entrained droplets.

A HEPA filter removes any residual particles.

A two-stage carbon adsorber removes residual organic vapors and mercury vapors.

An induced-draft fan draws off-gas from the desorber and creates a slight negative pressure throughout the system.

The outlet (vent) gas from the off-gas treatment system is discharged to the atmosphere through a roof vent. The desorber system operates at a slight negative pressure to prevent fugitive emissions. The negative pressure is maintained by using a small blower to pull the gases through the desorber and off-gas treatment system. A dry test meter and rotometer measure the vent gas flowrate and volume during a test period.

Pilot-Scale Thermal Desorption Results

The treatment raised the soil pH from 8.8 to 9.1 while the treated solids contained no moisture. The following data provides the results for PCBs removal.

Table I

Approximately 99.6 percent of the Aroclor-1254 and 99.9 percent of the Aroclor-1260 compounds were removed. Concentrations of 220,000 mg/kg and 390,000 mg/kg for the two respective Aroclors were present in the bag filter solids.

The table below provides mercury results for the thermal treatment.

Table II

The feed soil composite sample had a total concentration of 22,750 mg/kg and a TCLP value of 3.1 mg/kg. The treated soil composite contained 1,175 mg/kg, providing a 95 percent reduction, with a TCLP value of 0.032 mg/kg. Mercury was also recovered in the various process residual streams, with the bag filter solids having the highest concentration at 57,300 mg/kg and the scrubber liquid containing 171 mg/kg.

The following table lists the semi-volatiles found in the residual scrubber liquid solution.

Table III

Finally, the next table provides isotopic uranium and gross alpha/beta results for the feed soil, the treated soil, and the scrubber liquid.

Table IV

SOIL WASHING

Soil Washing is an ex-situ, water-based process that employs chemical and physical extraction and separation processes to remove organic, inorganic, and radioactive contaminants from soil. It is usually employed as a pretreatment process in the reduction of the volume of feedstock for other remediation processes. The contaminated soil is excavated and staged, pretreated to remove oversized material, and washed with water and, possibly, other cleaning agents to separate and segregate the contaminants. The process recovers a clean soil fraction and concentrates the contaminants in another soil portion.

The principal advantage of soil washing lies in its ability to concentrate contaminants in a residual soil as a pretreatment step, facilitating the application of other remediation processes. In reducing the volume of soil that must be treated, soil washing can reduce the overall cost. Soil washing performance is highly sensitive to site conditions. The process is most effective when applied to soils and sediments containing large proportions of sand and gravel and is less ineffective, or more costly when applied to soils having a high silt and clay content.

Bench-Scale Soil Washing Operations

Soil washing operations were performed to remove radionuclides, specifically uranium and thorium, from the thermally treated soil. The soil washing methods tested included gravimetric separation (sieving, flotation, and heavy liquid analysis) and chelant extraction. This phase of the study was separated into four separate tasks; 1) an initial particle size characterization, 2) bench-scale physical treatment/gravimetric separation, 3) bench-scale chelant extraction, and 4) pilot-scale flotation/chelant extraction. The "as received" soil sample was initially separated into 5 different size fractions (plus 2mm, 2mm-1mm, 1mm- 150mm, 150mm- 53mm, and minus 53mm) and each of these fractions were individually analyzed for mercury, uranium, and thorium.

This provided a distribution of the contaminants for each particle size fraction.

Heavy liquid separation was then used to characterize the presence of radionuclides (material with a specific gravity higher than soil) from the soil in two different size fractions; the coarse sand fraction (plus 150 mm) and the fine sand/silt/clay fraction (minus 150 mm). These fractions were determined based on the results of the characterization. Thegravimetric analysis uses a tetrabromoethane/methanol liquid media with a density of 2.8, which is between that of soil and heavy metal fragments. The soil floats on the liquid and is separated from the contaminated sink fraction.

A series of bench-scale chelant extractions were then performed trying carbonate/bi-carbonate, citric acid, and EDTA solutions, at varying concentrations, pH values, temperatures, and reaction times. Peroxide was also added to some of the extractions to try and change the uranium to the hexavalent form, thereby making the uranium more amenable to chelation. Approximately 50-g aliquots of coarse soil were reacted with each extractant in a 10:1 weight to weight (wt:wt) ratio of extracting solution to soil. At the conclusion of the reaction time, each soil slurry was filtered to separate the spent extracting solution from the soil solids. The spent extractant was collected for analysis. The soil solids on the filter (filter cake) were reslurried with 200 mL of deionized water and filtered. This was to reduce the residual extractant concentration and remove additional uranium remaining in the filter cake. The rinsate solution and extracted soil solids were collected separately for analysis.

Bench-Scale Soil Washing Results

The results of the initial particle size characterization for the soil showed that each of the five size fractions were analyzed for mercury, uranium, and thorium. These results clearly show that a majority of the contamination is present in the soil fines (minus #150). This fraction only represents approximately 28.4 percent of the total mass. By removing the soil fines, the average concentration of uranium can be decreased from 18,000 mg/kg to 12,000 mg/kg, a 33 percent reduction. The thermal treatment had previously removed 95 percent of the mercury concentration and lowered the PCBs level to below 100 mg/kg. Gravimetric separation provided a 48 percent reduction in activity for the coarse solids (plus 150 mm) while creating a highly contaminated fraction which was only 6.4 percent of the original mass.

The following data presents a series of bench-scale, chelant extractions performed using sodium carbonate, sodium bicarbonate, EDTA, citric acid, and peroxide. A single sulfuric acid extraction was also tested.

Table V

The 0.2 M EDTA, 4 hrs., pH 8.5 extraction provided the best results for a chelant removing approximately 58 percent of the uranium. The sulfuric acid removed over 90 percent, leaving 737 ppm of uranium in the soil. The 0.8 M carbonate/bi-carbonate extraction removed approximately 42 percent of the uranium. This result was close to the results provided by the EDTA extractions. Residual water treatment is much simpler with carbonate fluids, therefore, the carbonate extractions were preferred for the pilot study. The experiments with the peroxide did not seem to significantly improve the extraction.

Pilot-Scale Soil Washing Operations

From the characterization data and the heavy liquid analysis, a separation based on flotation was determined to be the best approach for pilot-scale treatment. A flotation column was constructed to separate the fine fraction (minus 150 mm) from the coarse fraction (plus 150 mm). A 4-inch diameter by 10 ft PVC, schedule #40 pipe was used. A 3-inch thick porous plug was placed in the bottom of the column with a PVC cap and served as a distribution plate. A 3/4-inch water hose fitting was then placed on the side of the column, 1-inch below the top of the porous plug. A second 3/4-inch hose fitting was placed on the side of the column, 8-feet above the porous plug. The soil was charged through the top of the column and the appropriate flow rate for the water was activated.

The flotation column acted basically as a hindered settling classifier. Hindered settling uses a rising current of water, introduced at the bottom of the vessel to expand the soil into a state of teeter. In this teetered state, the soil grains will classify themselves so the coarse grains will report to the bottom of the column and the finer particles will be dispersed to the top of the column. The flow rate for the column was determined from Stokes settling law formulas. The column flotation provided two process residuals, a fine soil slurry and a coarse soil fraction. The fines were allowed to settle and the water was decanted. The fines were labeled settled fines, and the water, flotation water. The coarse soil fraction was treated further by chelant extraction.

Using the data gathered from the bench-scale chelant extractions, a pilot-scale extraction was performed on 12 lbs. of the coarse soil in a 20 gallon reactor. The 20-gallon reactor was constructed of Carpenter 20, a high chrome, high nickel, stainless steel. The reactor was equipped with a with a 1 Hp, 1800 rpm Pfaudler drive and a custom fabricated agitator. The impeller supplied by Chemineer was designed to ensure proper mixing of the soil slurry. Soil was charged through a 4-inch nozzle on the reactor cover. After the extraction, the soil was allowed to settle, and the aqueous layers were removed using an M-2 diaphragm pump and a 1/4-inch teflon, liquid withdrawal tube.

It was determined that a series of two 0.1 M carbonate/bi-carbonate extractions would be performed for the pilot-scale, chelant extraction. The coarse soil was charged to a 20 gallon reactor with 15 gallons of the 0.1 M solution. The soil was reacted for 2 hours, the extractant was removed, another 0.1 M solution was added, the soil was reacted for another 2 hours, and then the extract solution was removed. The soil was then rinsed and slurried with wash water twice, and the washed solids were collected. This wash water contained a large number of fines. These washed fines were filtered and analyzed separately.

Pilot-Scale Soil Washing Results

At the conclusion of the pilot-scale thermal treatment and soil washing stages, a total of five process streams were present. Their descriptions are listed below:

- Flotation Water : water used to remove the fines from the soil
- Settled Fines : fines decanted from the flotation water
- Extract Solution : the combined carbonate/bi-carbonate solutions
- Washed Solids : coarse, extracted and washed solids
- Washed Fines : fine solids decanted from the extraction wash water

All five of the residual process streams, as well as the chemically extracted, non-washed solids, were analyzed for the following parameters:

Table VI

CONCLUSIONS

The data from the thermal desorption testing showed several unexpected results. Thermal treatment, at temperatures readily achievable by commercial thermal desorption systems, could not meet the 12 mg/kg treatment goal for onsite landfill of the Y-12 storm sewer sediments. The results of the bench-scale testing showed that treatment at 600C resulted in a residual mercury level of 80 to 140 mg/kg. This does meet the LDR criteria of 260 mg/kg. Unfortunately the pilot run did not duplicate this performance. The results of the RTA and the pilot-scale desorber have been very comparable in previous testing on PCBs, PAHs and on soil containing lower levels (100 to 200 mg/kg) of mercury. On this waste, while the PCB results of the RTA and pilot desorber were comparable, the treated sediments from the pilot run contained 1175 mg/kg of total mercury instead of the 100 to 150 mg/kg that were expected. This difference is probably due to inadequate purge gas flow in the pilot desorber. The treated sediments contained 0.032 mg/liter of TCLP mercury which is high compared to the RTA results, even when compared to the 350C test. The 350C RTA test showed less than 0.002 mg/liter of TCLP mercury in a treated sediment that contained over 3500 mg/kg of mercury. This implies that leachable mercury species (elemental mercury or mercury oxide) are left in the treated sediments from the pilot run at a ratio higher than in the RTA run. Since these species are volatile at the treatment temperatures, they are probably left in the soil due to inadequate purge gas flow. In the RTA, which operates on a batch cycle, the purge gas is a little hotter than in the pilot desorber and there is no potential for 'reflux' of mercury from the cold (feed) end of the tube to the treated soil end.

The soil washing and soil characterization results were not unexpected. All soil fractions, fines to coarse, were contaminated to a high degree, although the fines did contain higher levels of uranium than the coarse fractions. While the physical treatment by attrition scrubbing and gravimetric separation did lower uranium concentrations, the initial activity of this waste was too high for these treatments to achieve the treatment goal of 15 pCi/g. The chelant extractions were also not fully effective on this waste. The thermal treatment probably converts the uranium to the less soluble reduced uranite form. The thermal desorption treatment is not incineration and the atmosphere in the desorber tube is oxygen starved or pyrolytic. The size separation or fines removal using the hindered settling or flotation column was effective in reducing the mercury concentration in the coarse fraction to below the LDR criteria. While the thermal desorption process alone was expected to provide adequate mercury removal, the test showed that the combined treatment did produce a treated coarse fraction that met criteria for disposal at a commercial radioactive waste facility. This treated waste met LDR and TCLP criteria for mercury and the TSCA PCB limit. Additional testing is needed to determine if thermal treatment operating conditions can be modified to result in a treated soil that passes LDR mercury criteria without the additional soil washing step.

ABSTRACT

DETOXSM is a cocatalyzed wet oxidation process being developed as an alternative to combustive processes for the treatment of hazardous and mixed wastes. An effort is now in progress to fabricate and test a modular prototype unit capable of oxidizing 25. kg/hr of organic material. The prototype unit will be demonstrated at Savannah River Site (SRS) and at Weldon Spring Site Remedial Action Project (WSSRAP).

There are many low level and mixed wastes in the US Department of Energy (DOE) complex, as well as the public sector, which are organic in nature, or which contain hazardous organic compounds, and can be treated using DETOXSM as an alternative to combustion and other high temperature processes. Waste types to be considered were obtained from the mixed waste data bases and other sources maintained by the Department of Energy, in consultation with the demonstration sites and the Mixed Waste Focus Area.

Once waste types and surrogates for the demonstration were chosen, estimates were made of the emissions from the prototype unit when processing these materials. National Environmental Policy Act (NEPA) documentation was prepared and submitted. Environmental approval for the demonstration effort at SRS was approached through a waste water treatment unit approval. For waste treatment at WSSRAP (a CERCLA site) the substantive requirements for a RCRA Part B permit must be met. A sampling schedule was prepared for emissions from the prototype unit and the oxidation solution, and reviewed by the primary stakeholders in the demonstration.

Operational safety has been approached through modeling studies, flammability studies, HAZOP of the prototype unit, a Process Hazards Review conducted by SRS, preparation of Operating and Safety Manuals, preparation of Safe Operating Procedures for site review, and specialized training of the personnel who will be operating the unit.

BACKGROUND

DETOXSM is a catalyzed wet oxidation process which uses iron ions and homogeneous cocatalysts in an acidic aqueous solution. (1) Organic components of waste materials are oxidized in a stirred tank reactor at temperatures of 400. - 473. K and corresponding pressures of 100. to 800. kPa (atmospheric pressure to approximately 100. psig). Organic compounds are oxidized to carbon dioxide, water, and other simple products, e.g., HCl for chlorinated compounds. Non-volatile inorganic materials are

either dissolved into the oxidation solution or left as inert and/or produced solids suspended in the oxidation solution.

The DETOXSM process is being developed as an alternative treatment for mixed, TRU, and low level wastes in the US Department of Energy (DOE) complex with funding from DOE EM-50 through the DOE Morgantown Energy Technology Center and from the DOE Mixed Waste Focus Area. Demonstration sites are the Savannah River Site (SRS) and the Weldon Spring Site Remedial Action Project (WSSRAP). A prototype unit capable of oxidizing 25. kg/hr (dry weight, organic material) is being fabricated. The prototype unit will be capable of feeding both liquid and solid wastes, and of removing inert and produced solids from the oxidation solution during operation. The oxidation solution will be reduced to residue at the conclusion of a treatment campaign and stabilized for disposal. Shakedown tests and treatment of hazardous wastes/surrogates will be conducted at SRS, after which the unit will be transported to WSSRAP for treatment of low level mixed wastes.

In order to obtain as much value as possible from the demonstration effort, it was highly desirable to include representatives of many waste types in the DOE complex which could be treated with the technology. It was also necessary to obtain exclusions, approvals, and/or permits to operate the prototype unit in compliance with all applicable environmental regulations. Lastly, regardless of whether the prototype unit is found to operate effectively, it must be operated safely during the demonstration effort. These three areas: application, environmental compliance, and safety, are crucial to the demonstration of any waste treatment technology.

REPRESENTATIVE WASTE TYPES

The choice of waste types or surrogates to be treated in the demonstration was not trivial, since they had to be suitable for treatment by the process, available, suitable for the environmental permitting requirements of the demonstration, and representative of wastes in the DOE complex and elsewhere.

Common wastes suitable for treatment by the DETOXSM process are contaminated aqueous solutions, oils, solvents, combustible solids, organic sludges, soft debris, and excess chemicals. Water solutions, although of large volume in many instances, have less concentration of contaminants than many pure organic wastes, thus it was felt that pure organic compounds would be a more rigorous test of the DETOXSM process. This did not, however, eliminate treatment of aqueous streams in the demonstration.

A variety of matrices and contaminants are listed in the DOE mixed waste data bases (2,3), but representatives of these wastes may or may not be available for technology demonstration purposes at a particular site. At SRS, the selection of actual wastes available for treatment studies is limited. In many instances, waste surrogates will be used at SRS instead of actual wastes. Standard surrogate formulations for DOE wastes have been defined. (4,6) There are some advantages to the use of waste surrogates, namely, they are more well characterized than typical wastes, they can be prepared as a standard mixture which can allow more direct comparison of different processes, process limits can be more accurately defined, and they are not considered hazardous wastes for regulatory purposes. Disadvantages of surrogates are that they must be prepared, they are not actual wastes, and their preparation costs can be high. At WSSRAP, a good selection of wastes are available for treatment, including

solvents, oils, sludges, combustible solids, aqueous solutions, soft debris, and excess chemicals.

Waste or surrogate types also had to be treatable within the permitting arena of the host sites. For example, it would be extremely difficult, if not impossible, to obtain permission to treat listed wastes or materials containing radionuclides during the demonstration at SRS. Surrogates will be used instead.

A final critical consideration is whether the wastes or waste surrogates are considered representative of waste types across the DOE complex. The most value is obtained from the demonstration when more representative materials are treated. Under guidance from METC, the MWFA, and representatives from SRS, WSSRAP, and other DOE sites, the list of wastes and waste surrogates proposed for the demonstration was reviewed and matched against lists of mixed wastes and "hard-to-treat" wastes in the DOE complex. As a result of the review, an aqueous waste stream was added at SRS and the surrogate solids treated at SRS will be spiked with hazardous organic compounds.

Table I lists the waste surrogates and wastes to be treated in the demonstration.

Table I

ESTIMATED EMISSIONS

Delphi has estimated emissions from the prototype unit based on the waste surrogates and wastes to be treated, expected operational parameters for the prototype unit, literature values for vapor pressures, and the results of bench scale continuous oxidation studies.

HCl is the primary hazardous species in gaseous emissions from the prototype. Based on analyses of the product water from the bench scale continuous oxidation studies, there are also estimated to be principally three hazardous volatile organic compounds in the gaseous emissions from the prototype. Worst case calculations of emissions of these species under normal operating conditions gave the values shown in Table II. With an emissions stack height of 4.9 m (16. ft) or higher, none of the emissions values exceeded the regulatory requirements at either of the two demonstration sites. The organic compounds were well below regulatory concern levels. HCl emission was the controlling factor.

Table II

Levels of organic compounds in the product water from the prototype was the other primary environmental concern. Based on analyses of the product water from the bench scale continuous oxidation studies, estimates were made of the concentrations of organic compounds in the product water from each type of waste or waste surrogate to be treated at SRS. The full estimates are too extensive to be presented in this paper, but can be summarized by the volume of product water and the total amount of organic compounds estimated to be in the product water. These values are given in Table III.

Table III

The third type of emission from the DETOXSM unit is inert and produced solids. In the demonstration, some inert solids will be contained in the waste surrogates and wastes, but by far the largest volume of solids will be ferric phosphate produced from the oxidation of tributyl phosphate (TBP). TBP is an excellent simulant for wastes containing a large proportion of inert material, since for every weight of TBP oxidized approximately 60.% by weight ferric phosphate solids will be produced. Thousands of kilograms of inert/produced solids (mostly ferric phosphate)

will be filtered from the DETOXSM solution and rinsed during the demonstration, and this will provide valuable operational data on the unit's filtration system. The inert/produced solids are anticipated to be non-hazardous at SRS and low level radioactive at WSSRAP. At WSSRAP, the inert/produced solids will be treated by chemical solidification/stabilization before placement in the on-site disposal cell.

The other solid residue produced from the DETOXSM process is the DETOXSM solution residue. It is anticipated that the solution will be converted to solid form three times during the demonstration effort (once at SRS and twice at WSSRAP), each time resulting in 200. - 250. kg of ferric oxide solid containing the soluble inorganic compounds (including most of the toxic and radioactive metals) from the wastes which have been treated. An estimated 90,000. kg of wastes and waste surrogates will have been treated during the demonstration. The DETOXSM solution solid residue will be disposed of as hazardous waste at SRS, and treated by chemical solidification/stabilization for on-site disposal at WSSRAP.

PERMITTING ISSUES

Exclusions, approvals, and permits to operate the prototype unit in the demonstration are vital. Environmental regulations are complex and restricting in many instances for demonstration of new technologies. An example of this is the definition of the entire SRS as a "facility" for the purposes of the RCRA Treatability Studies Exemption. This ruling restricts the entire 30,000 acre site to a maximum of 250. kg/day waste treatment under TSE. One must be thorough in defining the regulatory situation at contemplated demonstration sites. As a project at a government facility, the demonstration must also be compliant with NEPA, which has required submitting information on the demonstration effort and its potential environmental impacts.

NEPA documentation was submitted to SRS as per the site Environmental Evaluation Checklist. WSSRAP determined that the demonstration was covered by existing NEPA documentation at their site. At each site the demonstration effort falls under a NEPA categorical exclusion.

At SRS, the regulatory path chosen was through the pre-treatment scenarios of the Clean Water Act, with approval of the prototype unit as an industrial wastewater treatment unit. It also would have been possible, although much more complex, to obtain a RCRA RD&D permit for the unit. Approval required submission of detailed water emissions estimates as described above, as well as a description of the process, the prototype unit, the demonstration site, spill containment measures, and the wastes and surrogates to be treated. Estimated air emissions from the prototype unit are well below State of South Carolina limits for toxic air emissions. Solid hazardous residues from the process will be disposed of in accordance with the requirements of the South Carolina hazardous waste management regulations.

At WSSRAP, a CERCLA site, the substantive requirements of a RCRA Part B permit must be met, although a formal permit is not required. Delphi has obtained a determination from EPA that the DETOXSM unit is permittable under RCRA as a miscellaneous thermal treatment system (Subpart X requirements). Estimated air emissions have been submitted to the State of Missouri Department of Natural Resources (MDNR) and air dispersion modeling of the emissions from the demonstration unit was conducted by Argonne National Laboratory for WSSRAP. A preliminary determination has been obtained from MDNR that no air emissions permit will be necessary

for the unit if it operates within estimated emissions parameters. Product water from the prototype unit will be pumped to WSSRAP's wastewater treatment facility, whose permit covers chemical treatment effluents. Solid residues from the process will be treated by chemical solidification/stabilization at WSSRAP's on-site facility and placed in an on-site disposal cell as per the WSSRAP Record of Decision (ROD).

OPERATIONAL SAFETY

Safe operation of the prototype is vital to the success of the demonstration effort, and various safety evaluation procedures are mandated by DOE.

The prototype unit design process has included a formal HAZOP with participation of representatives from the two demonstration sites. The HAZOP process first identifies the causes and consequences of non-standard operational conditions (high or low temperatures, pressures, flows, etc.), identifies existing design features which will alleviate the consequences, and then makes recommendations as to additional design features and operational procedures needed to further minimize consequences.

In addition to the HAZOP, SRS is conducting a Process Hazards Review (PHR) for the demonstration. The PHR is similar to a Safety Analysis Report (SAR), in that it will review all aspects of the demonstration effort from delivery and installation of the prototype unit, through shakedown and treatment operations, to final preparation, loading, and removal of the prototype unit from the site. The nature of the demonstration and size of the prototype unit do not warrant performance of a full SA.

Materials of construction have been an important component of prototype safety. It has been found, through materials compatibility testing and through operational testing in the bench scale continuous oxidation reactor, that tantalum has excellent compatibility with the DETOXSM process solution and its vapors. A tantalum-lined reaction vessel was operated for over 400. hours in the bench scale apparatus with no visible corrosion.(7) Materials tests performed at the Colorado School of Mines with the DETOXSM solution have shown very low corrosion rates for tantalum.(8) It is also known that titanium is somewhat compatible with the DETOXSM solution, but will not survive long exposures. Thus, parts of the prototype unit exposed to hot liquid DETOXSM solution are being constructed of tantalum-lined titanium. This provides, in effect, double containment for the process solution. Sensors between the tantalum lining and titanium shell will detect any breach of the tantalum lining. If a breach occurs, the titanium shell will contain the DETOXSM solution while it is cooled and removed so that the breach can be repaired.

The combination of organic compounds and oxygen in the DETOXSM reaction vessel results in flammability/explosivity safety concerns. A flammability limits study has been conducted by Delphi and Sandia National Laboratories to determine the flammable limits of organic compounds and oxygen under the conditions of the DETOXSM reaction vessel. An example of experimental runs is given in Fig. 1. The "nose" of the graph is the defined flammability limit. Numerous experimental runs have determined that, for volatile organic compounds, no flammability is possible below approximately 5.% by volume oxygen concentration in the headspace of the reaction vessel. This has defined a strict operating limit for oxygen concentration in the primary reaction vessel during operation of the unit.

Fig. 1

Dynamic simulations of the prototype unit have been conducted by the Chemical and Nuclear Engineering Department of the University of New Mexico. The simulations have identified the critical control aspects of the prototype unit. Key to safe operation of the process is control of the oxygen feed rate. Recommendations were made for various control interlocks, for positioning a fast-response oxygen sensor at the gas outlet from the primary reaction vessel with immediate oxygen feed shut off on a sensor reading of 1.% or higher, and for nitrogen blanketing the primary reaction vessel at start up. Also found to be a potential problem scenario was sudden loss of the cooling system. Loss of cooling would result in heat rise in the primary reaction vessel, reaching the design temperature of the vessel in about 13. minutes. From results of the bench scale continuous oxidation studies, shutting off the agitator will decrease the reaction rate of organic material in the reaction vessel by approximately an order of magnitude, which will slow resulting heat rise by approximately an order of magnitude and give approximately 2. hours before the reaction vessel's design temperature is reached. Stopping oxygen flow will also limit heat rise, since there is only about 1. hour's worth of ferric iron available to oxidize the organic in the vessel if it is not being regenerated. Thus, a combination of stopping the oxygen supply and the agitator should result in safe operation even in the event of total cooling system loss. As a emergency backup, the prototype has been designed with a quench tank of water which can be emptied into the primary reaction vessel to quench the oxidation reaction.

The Operating Manual for the prototype unit will consist of a description of the DETOXSM process and the prototype unit including mass balances for typical feeds, normal operating inventories, heat loads, and utilities, a description of the control system and control philosophy including alarm and automatic shut down conditions, safety features of the unit including personal protective equipment, routine precautions during unit operation, and location of safety equipment, the operating procedures including start up, steady state operation, upset conditions, and shut down, emergency procedures cross-referenced to alarm conditions with a "quick reference" chart, routine maintenance and calibration procedures, specifications of all parts, and an index to the manual.

An Environmental Safety and Health (ES&H) Manual is essential for any operations at the demonstration sites. The existing site ES&H document will be followed during the demonstration, which will provide compliance with DOE and OSHA rules and regulations. A Spill Prevention, Control, and Countermeasures (SPCC) procedure is required as per the requirements of 40CFR 112. Guidelines for preparing the SPCC are given in 40CFR 112.7. Some modification of the existing site Emergency Response Plan may be necessary to cover operation of the prototype unit. Existing radiation safety procedures will be followed at the WSSRAP. At WSSRAP, Safe Work Plans are required for on-site operations. The Safe Work Plan provides a description of the work to be done, the crew, equipment, a safety, health, and environmental risk assessment, preventive measures, any subtier contractors, a permit checklist, designation of Delphi's site safety representative, and the work crew signatures and date.

Training is an vital component for insuring safe operation of the prototype unit. In addition to basic training in safety awareness and proper use of personal protective equipment, all on-site operators will

have an accredited 40. hour HAZWOPR (emergency response) training course, and will be trained and certified in operation of the prototype unit as per OSHA Process Safety Management requirements. The process safety training will include typical operating procedures including normal start up and shut down, and emergency procedures including emergency shut down. The sites will provide operators with other necessary site-specific training. At SRS this will include RCRA and OSHA awareness, benzene training, mercury training, and hazardous energy safety training (including lock-out, tag-out procedures). At WSSRAP, radiation safety training will be added to the training regimen.

SUMMARY

Demonstration of the DETOXSM process for treatment of mixed wastes will be conducted with a modular prototype unit having an estimated throughput of 25. kg/hr (dry weight, organic material) of waste. The demonstration will take place at Savannah River Site and at the Weldon Spring Site Remedial Action Project. Wastes and waste surrogates for the demonstration have been chosen based on suitability, availability, regulatory requirements, and representativeness. Emissions and secondary wastes from the prototype unit have been estimated based on the wastes and waste surrogates to be treated. Environmental exclusions, approvals, and/or permits are being obtained. Safe operation of the prototype during the demonstration is being aided by safety reviews, ES&H procedures, emergency procedures, safe operating procedures, and operator training.

ACKNOWLEDGMENTS

Delphi Research, Inc. wishes to express our appreciation to DOE EM-50 (Office of Technology Development), DOE Morgantown Energy Technology Center, and the Rocky Flats Environmental Technology Site for funding the development of DETOXSM. We would also like to express our appreciation to Savannah River Site and the Weldon Spring Remedial Action Project for their help and support as demonstration sites for the DETOXSM technology.

AN INNOVATIVE PROCESS FOR CONTAINING TOXIC EMISSIONS WHILE THERMALLY TREATING MIXED WASTE (patent pending)

Kenneth A. Cruikshank
Wilbur L. Kephart
Foster Wheeler Environmental Corporation
Oak Ridge, Tennessee

ABSTRACT

The proposed innovative process for containing toxic emissions while thermally treating mixed waste is also designed to minimize waste handling for a board spectrum of solid and liquid feedstocks being processed separately or commingled in various shapes and sizes. Any potential toxic emissions present in the feedstocks or generated during treatment will be contained or recycled for further treatment. Two types of products will be produced: 1) industrial-grade commodities, and 2) solid products suitable for proper packaging for transportation and disposition.

The system is comprised of a series of technologies currently used in industry for throughputs which exceed current U.S. Department of Energy site-specific processing requirements. The use of a rotary kiln operating in series with a high temperature vitrification unit eliminates the inherent weaknesses of each unit operation. Consequently, a wider array of feedstocks can be processed more effectively with less energy being consumed.

Three additional unit operations have been added to offset the recognized limitations of existing off-gas cleaning systems: condensation, absorption, and membrane separation. Economic and operating considerations provide the incentives for utilizing enriched oxygen rather than combustion air. Cooled off-gases are used to replace the cooling effects of the nitrogen in the combustion air. The utilization of enriched oxygen coupled with off-gas recycling reduces the off-gases subjected to further treatment by 85%.

REGULATORY BACKGROUND

The environmental statutes and policies which most directly influence the selection of the subject technologies emanate from three environmental acts passed by Congress in 1990. In sum these three actsthe Clean Air Act Amendments of 1990 (CAAA), the Federal Facilities Compliance Agreement (FFCA) [PL102-39(b)], and the Pollution Prevention Act of 1990 (PPA) (42 U.S.C. 13101)redirected a portion of the U.S. Environmental Protection Agency's (EPA's) regulatory activities, expanded the scope of the existing environmental statutes and policies, and required federal facilities to conform to all applicable environmental statutes and policies.

Prior to 1990, the National Emission Standards for Hazardous Air Pollutants (NESHAPs) were used to establish air emission standards. This scheme became inoperable during the late 1980s when emissions standards were being established for compounds for which no risk assessment data was available and which could not be identified or qualified in the effluents from hazardous waste incinerators. Consequently, analytic results were inconclusive, and it was not possible to establish emission standards which could be enforced. As a result, Congress amended the Clean Air Act of 1970 (CAA) by abandoning this regulatory scheme. The new regulatory scheme installed was based upon "technology alternatives." Congress directed EPA to establish maximum achievable control technology

(MACT) standards on an industrial sector basis schedule to be completed by 1998.

It is clear that the CAAA has no direct bearing on federal facilities. Historically, most federal facilities had sovereign immunity whereby federal agencies were not required to follow either the federal or state laws due to the potential conflict between mission and compliance. The concept of sovereign immunity was sufficiently broad to prohibit one federal agency from forcing another federal agency to comply with federal statutes and policies. During the 1980s, Congress continued to empower state and local environmental agencies to act as the primary control mechanisms for federal environmental programs which could not be enforced at federal facilities. In a specific attempt to curtail sovereign immunity, Congress passed the FFCA which requires federal facilities to comply with all federal, state, and local solid and hazardous waste management requirements in the same manner and to the same extent as any agency subject to the Resources Conservation and Recovery Act of 1976 (RCRA). Also in 1990, Congress passed the PPA which, among other things, modified and cross-referenced the CAA, Clean Water Act of 1972 (CWA), and RCRA to develop greater continuity among environmental statutes. Section 6501 (42 U.S.C. 13101)(b) states:

The Congress hereby declares it to be the national policy of the United States that pollution should be prevented or reduced at the source whenever feasible; pollution that cannot be prevented should be recycled in an environmentally safe manner, whenever feasible; pollution that cannot be prevented or recycled should be treated in an environmentally safe manner whenever feasible; and disposal or other release into the environment should be employed only as a last resort and should be conducted in an environmentally safe manner.

This policy statement is consistent with the MACT objectives defined in the CAAA and defines the parameters for the proposed processing specifications. The only technical data used in this assessment were the data acquired from EPA-sanctioned studies conducted on hazardous wastes thermal treatment configurations. The detailed results of this broad assessment of hazardous waste incinerators have been presented elsewhere (1,2).

TECHNICAL BACKGROUND

Thermal treatment hazardous waste process specifications are determined by waste characterization and applicable regulations. During the last several decades, waste characterization requisites have been relatively constant while specifications for emissions have increased thirtyfold. Most recently, Congress has directed EPA to define MACT standards for some 20 waste characterization categories [Standard Industrial Classification (SIC) sectors]. Owners/operators are responsible for implementing MACT even if EPA does not comply with the congressional mandate in a timely manner.

The theoretically achievable emission limits for MACT standards approach zero for all three general emission regulatory categories: gross particulate matter, dioxin-like particulate matter, and ash leachability. Rotary kiln configurations were designated by EPA as the best demonstrated available technology (BDAT) for the treatment of hazardous waste during the early 1980s. Many of the configurations will not be able to qualify as MACT due to the inability to satisfy proposed standards for the dioxin-like particulate matter and ash leachability categories. BDAT hazardous waste treatment configurations will not qualify for mixed waste

MACT in most situations primarily due to the anticipated ash leachability criteria. There are interlocking technical relationships between ash leachability and gross and dioxin-like particulate matter; therefore, caution should be used in technically addressing these regulatory classifications independently. Much of the innovative technology recommended is complementary to one another as well as to an existing BDAT hazardous waste processing configuration.

Recently, EPA released a draft version of the Combustion Emissions Technical Resource Document (CETRED), which contains the initial technical analysis concerning emissions of dioxin/furans and particulate matter from certain types of devices which burn hazardous wastes (3). CETRED represents the first preliminary step in the development of technical standards governing emissions from hazardous waste combustors. Herein, the recommended approach utilized is to identify the best 12% (or best five sources, whichever is greater) and then determine the technology utilized to achieve the low emissions. These data are relevant since they potentially represent the lower bounds for the new MACT standards. CETRED displays a cumulative distribution of the hazardous waste industry gross particulate matter emissions. The critical values for the top 12% and median selected as representative of MACT are present in Table I.

Table I

These data imply that if the new gross particulate matter standards were set at the maximum emission rate for the top 12%, it would be necessary for the median emitter to reduce its emission rate threefold to tenfold to meet the new standards. Also, these data suggest that the unit operation selected for gross particulate matter removal should be capable of obtaining the maximum emission value for the median emitter before a dioxin-like particulate matter removal system is employed downstream since higher gross particulate matter values will reduce the effectiveness of the dioxin-like particulate matter removal system.

PROCESS OVERVIEW

The development criteria selected for the conceptual design of a MACT process which contains toxic emissions while thermally treating mixed waste are as follows:

1. Reduce the volume of flue gas generated.
2. Reduce the quantity of toxic emissions present in the flue gases generated.
3. Release only clean inert ingredients (industrial-grade carbon dioxide and nitrogen) from the system.
4. Recycle any potentially toxic substances not destroyed in the treatment process along with a small fraction of the uncleaned inert ingredients, including the water produced during treatment.
5. Produce a solid waste form that will not exceed the Toxicity Characteristic Leaching Procedure specifications, will satisfy nuclear waste product consistency tests, and will be in a form suitable for transportation and final disposition.
6. Minimize waste characterization, material handling and energy consumption.
7. Maximize operating flexibility and reliability while processing a nominal 30,000 tons/year through proven technology.

The baseline process configuration was a BDAT hazardous waste processing system consisting of a two-stage combustion system and an air pollution control system (APCS) (i.e., the K-25 TSCA Incinerator). This basic

process configuration was enhanced with a vitrifier to satisfy ash leaching requirements and with an extended toxic emission control system which contains the toxic substances and cleans the inert gases. Figure 1, Extended Toxic Emission Containment System, depicts the integrated process schematic. A BDAT hazardous waste processing configuration is shown on the left side of the schematic. The complementary extended toxic emission control scheme is reflected on the right side of the schematic. The proposed process utilizes oxygen, rather than air, as an oxidant. Oxygen utilization coupled with flue gas recycling reduces the stack emissions by 85%; thus, the extended toxic emission containment system needs to process only 15% of the normal flow rate (See Ref. 2 for details).

EFFECTIVE THERMAL TREATMENT

EPA designated rotary kiln technology as BDAT in the early 1980s after conducting field tests on eight full-scale commercial incinerators to validate the proposed trial burn analytic procedures. By definition, they are pre-RCRA incinerators. These emission results were reported by Trenholm, Gorman and Jungclaus (4). The significant average emission results were 1) destruction and removal efficiency (DRE) = 99.99%; 2) hydrogen chloride (HCl) = 99% removed; and 3) particulate matter = 180 mg/dry standard cubic meter (dscm) [0.08 grains/dry standard cubic foot (dscf)] released. In 1990 Oberacker reported similar average emission results obtained from 14 of the early trial burns (5). There are at least four polychlorinated biphenyl (PCB) incinerators operating in the United States. These incinerators must obtain a DRE greater than 99.9999%. Oxygen-enriched burners provide similar DREs (6). At the time of Oberacker's report, organic DREs were the primary concern, and with DREs greater than 99.99% the overall flue gas risk related evaluations were better than an acceptable health related incidence ratio of 1:106. During the mid-1980s, metal emissions in the flue gas, the bottom ash and the fly ash became a concern. Also, organic emissions in the bottom and fly ash were subjected to a more critical surveillance. One industrywide survey sponsored by EPA produced typical results (7). Some 43 organic priority pollutants were tested for in the solids residues from hazardous waste incinerators. Levels of organic priority pollutants were found in all solid residues, with the total quantity present varying between 10 ppm and 2000 ppm. Similar organic results were found in other studies while conducting metal analysis on the same residues (7,8). In these studies, ten metals were tested for, and some combinations of metals were found in all residues. The total quantities of these metals varied between 365 ppm and 44,763 ppm. When these organic and metal emission levels were integrated into the requisite risk evaluations via ash leachate migrating to groundwater, the overall risk evaluations produced health related incidence ratios between 1:105 and 1:106. To many, these health related incidence ratios represented an unacceptable risk. Although EPA designated stabilization as BDAT for waste metal treatment, it was quickly demonstrated that vitrification produced a more homogeneous, nonleachable product. As a consequences, much development work was performed to demonstrate that the vitrifier should replace the rotary kiln as BDAT for hazardous waste thermal treatment. This mode of operation was not universally successful due to the increased material handling/preparation complexities introduced into the overall process, coupled with a severe reduction in the types of wastes which could be economically processed. The proposed process eliminates these processing

complexities and retains the desirable operating flexibility features associated with rotary kiln operations. This is accomplished by operating the rotary kiln and the vitrifier in tandem as shown in Fig. 2, Traditional vs. Novel Thermal Treatment Configuration.

Figure 2 shows that the modifications to a BDAT rotary kiln process required for tandem operations with a vitrifier are straightforward. Unless large quantities of relatively dry, low British thermal unit (Btu) solids are being used as feedstock, the vitrifier can be located in the space utilized by the ash conveyers in an existing BDAT configuration. The proposed innovative thermal treatment process involves modifying the operating philosophy because the thermal treatment process is being converted from a two-stage to a three-stage process. This transition requires the kiln to be sized and operated differently. Traditionally, in the two-stage thermal treatment process, a kiln has been sized to achieve maximum heat transfer, which in turn provides the maximum treatment volume and throughput at the expense of several parameters currently recognized as severe toxic emission generation and containment constraints. In the innovative three-stage thermal treatment process, the major function of the kiln is to separate the waste into two phases: solids and vapors. Most of the thermal treatment reactions will be conducted in the other two reactors. Further, the phase separation activity must be conducted in such a manner as to minimize particulate carryover because it has been demonstrated that the presence of mineral particulate matter interferes with completing desirable reactions downstream which are associated with the elimination and separation of dioxin-like and radioactive particulate matter. In sum, in the innovative three-stage thermal treatment process, the major purpose of the rotary kiln is twofold: 1) to prepare the feedstock for the other two thermal reactors and 2) to provide adequate operating flexibility to offset the inherent weakness in the existing waste characterization methodology. Both of these objectives can be achieved at lower operating temperatures. With the proposed three-stage thermal treatment configuration, the normal exit gas temperature will be in the 1200F-1400F temperature range.

Another important feature is the manner in which heat is introduced into the rotary kiln. Traditionally, heat was introduced through a burner on the front face of the kiln in a manner to obtain maximum heat transfer. Due to the basic kiln configuration, bed burning and high water content in the feedstock, temperature differentials greater than 800F were routinely observed. These extreme temperature differentials are an indication of uneven heat transfer, which in turn creates unsteady state thermal reactions. During such transient periods, excessive particulate matter is conveyed into the flue gases, and the solid residence time may not be sufficient to volatize all organics present. The proposed process utilizes a staged cyclonic heat transfer device to ensure effective heat transfer, to provide steady state thermal reactions, and to minimize gas conveyance of mineral particulate matter out of the kiln. Figure 3, Staged Cyclonic Heat Transfer Device, shows this apparatus. The staging concept provides operating flexibility to adjust for feedstock variations not detected in the waste characterization. The use of multiple burners allows the use of high turbulent velocities which are necessary to obtain the homogeneous mixtures required to obtain high DREs with minimal bed disruption. Minimal bed disruption produces minimal gas conveyance of mineral particulate matter. The utilization of the staged cyclonic heat transfer device allows most of the combustion reactions to occur near the

top of the kiln. By introducing the oxidant perpendicular to the direction of the natural draft, a slight cyclonic effect is introduced whereby the flue gases, nearly deplete of oxygen, transverse the top of the bed carrying a thin layer of exposed solid particles to the hot refractory wall opposite the solid bed which does not lie at the bottom of the rotating cylinder. This cyclonic action increases solid bed burnout efficiencies, yet it is not sufficiently severe to create significant increases in airborne particulate matter which could be a carrier of substances that interfere with the destruction of dioxin-like compounds.

From the previous discussion, it is possible to observe that combustion criteria are no longer prominent for sizing and operating the rotary kiln. Rather, the sizing and operating requisites emanate more from direct drying and calcination criteria. This mode of operation is preferred because it reduces particulate carryover, minimizes transient gas flows, allows for a less vigorous waste characterization, and provides a larger operating envelope.

When the hot solids are fed directly into the vitrifier, two forms of energy conservation are utilized: 1) the heat content residing in the solids is immediately utilized, and 2) the vapors are not unnecessarily elevated to superheated conditions before being cooled to ambient conditions. Further, since the hot solids are fed by gravity into the vitrifier, material handling equipment is not required, and workers are not exposed to hot intermediate hazardous waste products. All of these activities enhance the primary objective for utilizing the vitrifierto produce a nonleachable stable ash. The prospects for metal refining are not precluded. In all cases, the ensuing product(s) can be produced in a form suitable for transportation and final disposition.

EXTENDED TOXIC EMISSION CONTAINMENT SYSTEM

The primary purpose of the extended toxic emission containment system (ETECS) is to contain dioxin-like particulate emissions. The primary purpose of the BDAT APCS is to remove the gross particulate matter. There are numerous types of APCSs in service. Table I, Gross Particulate Matter, shows the spectrum of their on-stream performance. In part, APCS performance is a function of the particular configuration in service and the manner in which it is operated. Waste composition is a common component impacting the performance of all APCSs. The two most critical parameters are the amount of particulate to be removed (grain loading) and the particle size distribution. As indicated in the thermal treatment discussion, the manner in which the thermal treatment reactors are operated impacts both the amount of particulate matter conveyed in the off-gases and the corresponding particle size distribution as well. A more complete discussion of these relationships can be found in Ref. 9.

The most sensitive design and operating parameter is the amount of particulate matter present in the feedstock, which is less than 1 micron. All of the traditional APCS configurations begin to experience a loss in collection efficiency in this particle size range. Further, the collection efficiency drops dramatically when the particulate matter is less than 0.5 micron. most of the dioxin-like particles are less than 0.01 micron; therefore, different unit operations must be used to contain these particles. From a design viewpoint, there will be particles present in the ETECS influent in the range between 0.0001 and 1 micron which must be separated for reprocessing. It is imperative that an APCS is operating upstream of the ETECS to remove most of the particulate matter greater

than 0.5 micron. The primary reason for distinguishing between gross and dioxin-like particulate is to draw attention to the following facts: 1) different processing principles must be applied to separate and contain the particles in these two distinct particle size ranges, and 2) the larger particles must be removed before an attempt is made to remove the smaller particles.

Fig. 1

Fig. 2

Fig. 3

The right side of Fig. 1 shows the ETECS. Because oxygen and flue gas recycle are incorporated into the overall design, the gas flow to the ETECS is only 15% of the gas flow through the thermal treatment reactors and the APCS. The nominal composition of the gas flow to the ETECS of water vapor (36%), carbon dioxide (40%), nitrogen (16%), oxygen (8%), and sundry trace substances (less than 0.1%). The processing objective of the ETECS is to clean and release substantial quantities of industrial-grade nitrogen and carbon dioxide. All other substances will be recycled to the most appropriate location in the process. The ETECS is comprised of three different unit operations operating in series: condensation, absorption, and membrane separation. All of these unit operations are used throughout industry at greater throughputs and in more corrosive environments; however, they have not been used in the proposed sequence.

Condensation is utilized as the first stage in the ETECS to remove the water vapor, which represents over one-third of the influent to the ETECS. Equally important, a significant fraction of the particulate matter will be removed when the water is condensed since a portion of this particulate matter will be physically or chemically bound to this water. Another fraction of the particulate matter will become encapsulated during the condensation process. In addition to flow reduction, condensation is very effective in removing particle sizes in the 0.01-1 micron range. Periodic excessive quantities of particles in this size range could reduce the long-term effectiveness of the absorption and membrane separation processes. Such transient conditions have minimal impact on the condensation process.

Absorption is the second unit operation in the ETECS. Its primary use is to clean and remove the carbon dioxide, which represents nearly two-thirds of the remaining off-gases. An organic solvent is used to absorb the carbon dioxide. The organic solvent will also absorb and adsorb trace amounts of particulate matter which is removed during the regeneration step. This portion of the process is not reflected on the process schematic since only small periodic flows are involved. After the clean carbon dioxide is separated from the solvent, it is sampled and analyzed prior to release. Should the product not meet the required specifications, it will be reprocessed.

It should be noted that membrane separation technology can be used to clean carbon dioxide as well. Absorption was selected as the second cleaning stage after condensation because absorption is more effective in the presence of oversized particles, where particles greater than 0.005 micron are considered to be "oversized." Also, trace amounts of acid gases may be present periodically. Although some of these constituents have a particle size less than 0.005 micron, they could have a long-term deleterious effect on certain types of membranes. Over the long term, these constituents can be processed more effectively in an absorption system.

The third unit operation in the ETECS is membrane separation, which has several applications all with small throughputs of relatively clean material. The primary application is to separate the clean nitrogen from the absorber off-gases, which are then recycled. The absorber off-gases represent about 14% of the influent to the ETECS. About one-third of these off-gases will be recycled after the nitrogen is separated from these off-gases. The clean nitrogen will be sampled and analyzed prior to release. All nitrogen products not meeting specification will be recycled.

Membrane separation is a complementary technology which is sized according to particle inlet concentration, particle size distribution, and desired particle outlet concentration. Table II, Membrane Material vs Particle Size Distribution Range, shows the nominal particle size range for three common categories of membrane materials.

Table II

There is an overlap reflected in these particle size ranges because separation efficiency is not constant over the entire range.

Membrane separation units consist of a cascade of common components arranged to provide the desired effluent(s). The most basic element in a membrane separation unit is the bundle of membrane material wrapped around a tube in multilayers separated by spacers. Several of these tube bundles are placed within a steel tube and capped. The caps contain three openings: feed, permeate (the material passing through the membrane), and retentate (the material contained by the membrane). These cylinders are then arranged in a myriad of configurations to achieve the desired concentrations in the streams to be cleaned. Fig. 4, Typical Membrane Cylinder Configurations, shows examples of the manner in which these cylinders are commonly arranged. There can be multiple cylinders in a staged configuration. Normally, all cylinders in a multiple-cylinder stage contain the same type of membrane material. On occasion, different material may be used in different states. Figure 4c shows the configuration used to separate the nitrogen from the other recyclable substances. Multiple recyclable streams are shown since all substances may not go to the same treatment reactor.

Fig. 4

SUMMARY

The successful containment of toxic emissions while thermally treating mixed waste emanates from the utilization of three thermal reactors in series coupled with oxygen utilization and flue gas recycling. This mode of operation reduces the gaseous effluents by 85%. The ensuing reduction in the quantities of flue gases emitted makes it economically affordable to use proven technologies to clean these effluents to environmentally acceptable levels.

The incremental capital cost for making these proposed enhancements to a traditional BDAT configuration is estimated to be less than 20% of the traditional BDAT plant site cost. The major increase in operating cost will be reflected in the power cost required to vitrify the solids and pressurize the residual flue gases for processing in the extended toxic emission containment systems. A reasonable estimate of these operating costs is the cost of 1.25 MW/ton of solids processed.

ABSTRACT

Hazardous waste operating permits issued under the Resource Conservation and Recovery Act (RCRA) often impose requirements, typically by reference to the original permit application, that specific components and equipment be used. Consequently, changing these items, even for the purpose of routine maintenance, may first require that the owner/operator request a potentially time-consuming and costly permit modification. However, the owner/operator may demonstrate that a modification is not required because the planned changes are "functionally equivalent," as defined by RCRA, to the original specifications embodied by the permit. The Controlled-Air Incinerator at Los Alamos National Laboratory is scheduled for maintenance and improvements that involve replacement of components. The incinerator's carbon adsorption unit/high efficiency particulate air filtration system, in particular, was redesigned to improve reliability and minimize maintenance. A study was performed to determine whether the redesigned unit would qualify as functionally equivalent to the original component. In performing this study, the

following steps were taken: a) the key performance factors were identified; b) performance data describing the existing unit were obtained; c) performance of both the existing and redesigned units was simulated; and d) the performance data were compared to ascertain whether the components could qualify as functionally equivalent.

In this case, the key performance data included gas residence time and distribution of flow over the activated carbon. Because both units were custom designed and fabricated, a simple comparison of manufacturers' specifications was impossible. Therefore, numerical simulation of each unit design was performed using the TEMPEST thermal-hydraulic computer code to model isothermal hydrodynamic performance under steady-state conditions. The results of residence time calculations from the model were coupled with flow proportion and sampled using a Monte Carlo-style simulation to derive distributions that describe the predicted residence times. The results showed that the redesigned unit, although physically different in many aspects, is equivalent in performance to the existing unit, thereby obviating the need to seek a permit modification. By using this approach to demonstrate the functional equivalency of the redesigned unit, it is estimated that $1 million allocated to perform a trial burn was saved.

INTRODUCTION

The Los Alamos National Laboratory's (LANL's) Controlled-Air Incinerator (CAI) has recently undergone maintenance and improvements that involved replacement of components. The CAI carbon adsorption unit, in particular, was redesigned to improve reliability and minimize maintenance requirements. This study compared the hydrodynamic performance of the existing activated carbon adsorption unit/high efficiency particulate air (HEPA) filtration system (the system) and the proposed upgrade of the system. The purpose was to determine whether the changes can be considered "functionally equivalent" pursuant to regulations promulgated under the Resource Conservation and Recovery Act (RCRA) at 40 CFR 270.2 (1).

The CAI was originally intended to process small amounts of waste for research purposes only, so the specifications for the materials of construction did not consider the rigors and stresses of continuous operation, particularly those relating to corrosion. The existing carbon adsorption unit is constructed of low-carbon steel, a corrosion-prone material. Also, the angle of the carbon bed is thought to inhibit efficient filling of the bed with carbon and allows carbon particles to escape through the screen, which may encourage bridging of the media.

In order to maintain the current operational parameters and minimize the potential for a major RCRA permit modification, as discussed below, the proposed unit design is based on the same primary design criterion as the existing unit, namely, a gas-carbon contact time of 0.5 second. This criterion is based on Nuclear Power Plant Air Cleaning Units/Components, Section 5.2.2, "Adsorber Design," which requires that for the removal of gaseous iodine the minimum residence time of a gas stream in an adsorbent be 0.25 second (2). The current unit is designed to a minimum residence time of 0.5 second because a safety factor of 2.0 was used in the original design.

REGULATORY CONSIDERATIONS

To burn hazardous and mixed radioactive waste, the CAI must operate under the provisions of LANL's Hazardous Waste Facility Permit issued by the New Mexico Environment Department (NMED) (3). Under RCRA, any proposed

changes to a permitted facility must be evaluated to determine whether the changes require a modification to the permit. The requirement for a permit modification and its magnitude, or "Class," are determined using specific criteria. The general criteria that define the modification class are specified in 40 CFR 270.42(d)(2) as follows:

i) Class 1 modifications apply to minor changes that keep the permit current with routine changes to the facility or its operation. These changes do not substantially alter the permit conditions or reduce the capacity of the facility to protect human health and the environment. In the case of Class 1 modifications, the Director may require prior approval.

ii) Class 2 modifications apply to changes that are necessary to enable a permittee to respond, in a timely manner, to,

A) Common variations in the types and quantities of the wastes managed under the facility permit,

B) Technological advancements, and

C) Changes necessary to comply with new regulations, where these changes can be implemented without substantially changing the design specifications or management practices in the permit.

iii) Class 3 modifications substantially alter the facility or its operation (1).

Each class requires a different level of response from the permittee and different levels of public involvement, Class 3 modifications being the most rigorous.The carbon adsorption unit is not specifically described in LANL's permit as it is currently written (3). Therefore, a physical change to this particular apparatus does not automatically require a modification to the permit unless the NMED determines that it causes or justifies a change to the permit conditions(40CFR 270.41(a)(1)) (1). The only permit condition that applies to the carbon adsorption unit is a requirement to replace the spent carbon; this requirement will still be met after the proposed unit is installed.

The primary concern of CAI staff was the potential for the upgrade to require a Class 3 permit modification, as specified in Appendix I to 270.42, item L(3).

Modification of an incinerator, boiler, or industrial furnace unit by changing the internal size or geometry of the primary or secondary combustion units, by adding a primary or secondary combustion unit, by substantially changing the design of any component used to remove HCl/Cl2, metals, or particulate from the combustion gases, or by changing other features of the incinerator, boiler, or industrial furnace that could affect its capability to meet the regulatory performance standards.... [This is a Class 3 modification]. (1) (emphasis added)

The carbon adsorption unit is designed to remove radioactive isotopes of iodine, which is neither a particulate nor a metal. Hydrogen chloride (HCl) and chlorine (Cl2) are removed in the venturi scrubber and the absorber column, respectively. The unit may contribute to the removal of organic compounds, but its capacity in this regard has never been assessed, except through the overall destruction and removal efficiency (DRE) established for the entire CAI during the trial burn. That is the root of the problem for the CAI, because the last part of the citation above describes any change that could affect the ability to meet performance standards.

However, if the facility can demonstrate that the upgraded equipment is functionally equivalent to the equipment that it replaces, there is no

longer a basis for assuming that the change would affect performance. Functionally equivalent components are defined in the regulations as follows:

> Functionally equivalent component means a component that performs the same function or measure and which meets or exceeds the performance specification of another component (40 CFR 270.2).

In fact, upgrading with functionally equivalent components is a specific type of Class 1 modification listed in Appendix I of Part 270:

> Equipment replacement or upgrading with functionally equivalent components [is a Class 1 modification] (1).

To better define the circumstances that constitute this type of modification, the EPA stated in the preamble to the revised 40 CFR Part 270 that:

> Under Item A(3), permittees are able to make routine equipment replacements that are necessary for the continued operation of the facility ... (however) some permit conditions may inadvertently create restrictions by incorporating portions of the Part B permit application by reference. For example, if a permit incorporates a design drawing by reference which specifies a particular piece of equipment ... then to replace the item with anything other than the original model might require a permit modification. Such an item may not be available ... or the permittee may prefer to replace it with an improved version ... Therefore, if it is necessary to include design drawings in permits, the permit condition should also allow minor deviations from the design without a permit modification (although the Director may want to have the permittee send the revised design to the Agency to maintain a current file on the facility) (53FR 37924-37925, September 28, 1988) (4).
>
> Therefore, Item A(3) in the Appendix provides that equipment replacement or upgrading with functionally equivalent components is a Class 1 change (53 FR 37924, September 28, 1988) (4). (emphasis added)

It is clear, then, that if the proposed change to the design of the carbon adsorption unit could be demonstrated to be a replacement with a functionally equivalent component, it would not require a modification to the existing permit and at worst would have to follow the procedures for completing a Class 1 modification.

For the CAI, the difficulty arises from the unique nature of each unit's design. Under normal circumstances, manufacturer's performance data or other specifications could be used to demonstrate functional equivalency. However, because each unit was custom designed for application in the CAI, this was not possible. Instead, the existing and proposed unit designs were modeled using numerical simulation to perform a relative comparison of performance.

NUMERICAL SIMULATION

The time that moving gas resides within a process unit, or any delineated portion thereof, can be referred to as the gas residence time. For the system being analyzed, treatment of the offgas occurs when it is in contact with the adsorption medium, which is granular activated carbon. This leads to the conclusion that gas residence time within the carbon bed is the primary criterion for comparison between competing designs. Also of importance is the relative distribution of gas flow or flow proportion over and across the carbon bed. For the purposes of this analysis, flow proportion was defined as the fraction of the total gas flow moving through the unit at any given time, and was calculated by dividing the flow in a unit cell by the total flow. Values of gas

residence time and flow proportion cannot be calculated directly. Rather, numerical simulations were performed that provided gas velocities and pressure drops throughout the internal volumes of both unit designs. The gas velocities and their distributions resulting from these simulations were then used to calculate gas residence time and flow proportion. These parameters were compared using a Monte Carlo-style sampling technique to determine the relative steady-state hydrodynamic performance of the two designs, which enabled the determination of functional equivalency.

The hydrodynamic behavior of the two unit designs was modeled using several numerical simulations developed with the TEMPEST thermal hydraulic computer code (5). The models simulated the physical configuration and operation of the two designs under actual operating conditions. Physical configuration data were taken from drawings of the two designs (6,7,8,9). Typical operating conditions and additional information on the operation of the CAI were taken from a report produced by T.K. Thompson, Inc. (10)and various data transmittals from CAI personnel. Operational data were also available from the CAI RCRA trial burn, conducted in 1989, which described operating conditions in the existing unit (10,11).

Several assumptions were necessary to complete the calculation of the gas residence times and flow proportions. The primary assumptions are listed below.

Gas residence time is equivalent to treatment capacity.

Gas residence time distributions correspond to the numerical simulation predictions of flow.

The effects of nonuniform flow distribution are accounted for by using flow proportion as the measure of probability that the gas will achieve a particular residence time.

Minimum residence time is equal to the minimum gas flow path length divided by the gas velocity component orthogonal to the carbon bed screen.

Minimum gas flow path length is defined by the shortest path across the carbon bed (i.e., the carbon bed thickness).

Carbon bed cells in the region of the mid-axial barrier in the proposed cylindrical design can be ignored because of the lack of significant radial flow and the subsequent overestimation of gas residence time.

The results of the numerical simulation of the hydrodynamic performance of the existing and proposed unit designs, in the form of flow and relative pressure distributions, are shown in Figs. 1 and 2.

Fig. 1

Fig. 2

FUNCTIONAL EQUIVALENCY DETERMINATION

As mentioned previously, a statistical technique was employed to determine the distribution of residence times for the proposed and existing unit designs. Volumetric flow proportion was used as a measure of probability to characterize the residence time distribution for each unit. Monte Carlo-style simulations (i.e., random sampling of the distributions) were used to statistically describe the distributions. Flow proportion was used in the analysis to describe the frequency of occurrence of residence times in each unit. The proportions of flow at a given residence time were summed across all spatial elements in the carbon bed models and used to describe a probability density function for the distribution of residence times for each unit design. Because of its cylindrical, double-pass design, the approach used to determine the

distribution of total residence time for the proposed unit was more complex than for the existing unit. The distributions of residence times for the top and bottom halves of the unit were sampled separately and then summed. This approach is predicated on the assumption that the residence times in the top and bottom halves of the proposed unit design are independent.

Figures 3 and 4 illustrate the distribution or probability of gas residence times for the existing and proposed unit designs. Analysis of these distributions indicated that the proposed unit has a significantly greater proportion of flow that exceeds the 0.5 second requirement than the existing unit. The distributions also indicated that the volumetric flow of gas was better distributed in the proposed unit, thus offering potentially more efficient usage of carbon and a larger margin of safety for contaminant breakthrough. Based on the numerical simulations and subsequent analysis, the proposed design was determined to be functionally equivalent to the existing carbon adsorber unit in the CAI.

Fig. 3

Fig. 4

CONCLUSION

Because of the unique design and application of the carbon adsorber, manufacturer's performance data or other specifications could not be used to demonstrate functional equivalency. This necessitated a numerical simulation of the relative hydrodynamic performance of each design. The results of this simulation coupled with a statistical simulation technique provided the data necessary to determine that the proposed unit design was indeed functionally equivalent to the existing design. The approach used in this case successfully avoided the need for a potentially time-consuming and costly modification of the facility's hazardous waste operating permit. It is estimated that approximately $1 million was saved by avoiding a trial burn to evaluate the proposed unit's performance. This approach, in effect, sets a precedence for application at other permitted units to meet the compliance requirements of RCRA while minimizing costs and potential delays.

ABSTRACT

The lease of a comprehensive suite of radiometric assay systems is proposed as an attractive option for meeting the monitoring requirements of short-term decommissioning or waste retrieval operations. The merits of leasing are that a cost effective, guaranteed, high quality service is provided using state-of-the-art technology operated by skilled technical personnel. A suite of instruments have been developed as a result of significant operational experience which are capable of meeting the full range of the monitoring needs of decommissioning operations from planning through execution to final removal and characterization of the waste. These instruments have several common design features such as transportability, ease of decontamination etc., which make short-term leasing a viable option.

INTRODUCTION

Meeting the increasingly stringent requirements for characterization and assay of radioactive waste materials (e.g. from decommissioning operations) requires the use of sophisticated and complex radiometric monitoring systems. In many cases the plant operator has a continuing, long-term need for such monitoring systems and this need is best met by the conventional approach of purchase and operation by his own personnel. Where the requirement for the monitoring system is short-term, however, the operator may see little value in ownership and still less in providing the trained manpower.

BNFL Instruments Ltd. (BIL) and Pajarito Scientific Corporation (PSC), two wholly owned subsidiaries of the BNFL group of companies, have developed a solution to this problem which involves the lease of a comprehensive suite of highly mobile monitoring systems supported by skilled technical personnel. This approach offers a high quality, low risk service to the customer which will help to plan decommissioning operations and will meet all the relevant regulatory requirements. The

radiometric systems are all based on state-of-the-art technology and are designed to meet all the customers monitoring needs from initial survey of gamma "hotspots" and in-situ measurement of residual fissile material within the plant through to accurate assay of the final packaged waste materials.

OPERATIONAL EXPERIENCE

The operational experience which has led to the ability to provide this service includes the decommissioning in recent years of three redundant plutonium (MOX) facilities at the Sellafield reprocessing plant in Cumbria, UK. The three facilities were a co-precipitation plant, a dry granulation plant and a fast reactor fuel fabrication plant. The MOX fuel from these facilities had plutonium enrichments of up to ~30% PuO_2. In total some 60 individual Pu contaminated gloveboxes and vessels have been removed from these facilities and processed as TRU waste. As part of this extensive programme, decommissioning managers and engineers have worked closely with members of BIL to formulate an integrated dismantling and NDA monitoring strategy. This has resulted in the development of a "family" of radiometric systems aimed at providing cost effective, simple and accurate measurements of TRU waste to meet the decommissioning manager's needs. The overall decommissioning/NDA strategy and the radiometric instruments used to make this strategy possible are shown in Fig. 1.

All of these instrument systems have several features in common which ensure that they will function correctly for prolonged periods in a plant environment and that after completing a programme of monitoring they can easily be relocated and used for subsequent projects. For example, where the entire instrument is not readily transportable, modular construction has been used to allow for easy relocation. All the instruments are plant ruggedised (i.e. designed to withstand a certain level of rough treatment), are sealed wherever possible and have surfaces which allow for easy decontamination. Specific attention has been paid to preventing electrical noise problems e.g. through the use of RFI-screened detector cables and automatic data quality checking. The instruments all incorporate periodic self check features (which typically involve measurement of a standard source) to ensure the correct functioning of the instrument. All the assay type instruments provide "most probable" Pu mass values which can be used for material accountancy purposes and "worst case" values which are used for criticality control and are calculated by adding the total measurement errors (i.e. statistical counting uncertainties and systematic error components) to the "most probable" value.

Fig. 1

PRE-DECOMMISSIONING PLANNING

The overall decommissioning strategy for Pu plants usually involves first removing waste from within the process gloveboxes and vessels, then removing the gloveboxes themselves and finally removing any remaining contaminated areas of floors and walls within the building. This strategy requires good planning prior to the commencement of decommissioning operations. Remote identification and quantification of radiation hot-spots in gloveboxes allows clean-up teams to effectively target these areas for early decontamination, resulting in an overall minimization in dose uptake throughout the decommissioning programme. BIL's easily transportable RADSCAN 600 system has been specifically designed to

achieve this task by combining real-time visual and radiometric surveys of individual gloveboxes or entire process lines.

The RADSCAN 600 system (Fig. 2) consists of a CsI (Tl) scintillation detector and photodiode, with a tungsten collimator (which gives angular resolutions between 2 and 9), which is mounted so as to have the same field of view as a high definition colour CCD camera. The scanning head in which the detector and camera are mounted is sealed to IP65 in order to aid decontamination using a water jet. The system has a remote workstation with a colour monitor and VCR for viewing and recording RADSCAN surveys and a PC which controls the operation of the system including the pan and tilt of the scanning head.

From its deployment tripod the RADSCAN system provides real time 2D mapping of the spatial distribution of radioactive material in vessels and gloveboxes. A 3D map of radiation hotspots within a glovebox can be obtained by applying a triangulation process to the results of scans taken from two different locations.

Fig. 2

The location of residual quantities of plutonium of the order of tens of grams have been identified within redundant gloveboxes using the RADSCAN system and the triangulation technique. Intrinsic photodiode noise means that the RADSCAN system is inappropriate for the detection of radiation below approximately 100keV. Development work is currently underway to improve the instrument's performance in this energy range hence allowing, for example, 60keV radiation from 241Am to be detected.

INITIAL ASSAY OF WASTE REMOVED FROM GLOVEBOXES

Following the location of significant residual plutonium hold-up, the decommissioning teams target these areas for clean-up and remove the residual plutonium via bagging ports. TRU waste removed from gloveboxes in this fashion can then be rapidly assayed for nuclear safety purposes by the TRU-D measurement system (Fig. 3), a mobile instrument which is specially designed to monitor small, packaged waste items. The TRU-D system is a self contained, stand alone instrument system in which all the components (e.g. assay compartment, detectors, cables, electronics and user interface) have been integrated into a single mobile unit (dimensions 1.65m high x 0.71m wide x 1.55m long) which moves under the power of its own internal battery.

The TRU-D system is normally configured to determine the Pu mass via a total neutron counting measurement so that assay times are minimised (5 minutes or less). However this technique may give inaccurate results if the isotopic or chemical composition of the Pu is not known. In such cases the TRU-D system can be configured to perform the Pu assay using the Neutron Coincidence Counting (NCC) technique and to incorporate High Resolution Gamma Spectroscopy (HRGS) using a Hyper Pure Ge detector. The Pu isotopic composition can be determined form the recorded gamma spectrum through the use of BIL developed and tested algorithms or through the use of the MGA code (1).

The combination of these two techniques (NCC & HRGS) results in a Pu assay which is independent of the plutonium isotopic or chemical composition. With the TRU-D system configured to perform a combined NCC and HRGS assay, total measurement errors of below 20% are usually achieved for samples containing a few grams of Pu.

Fig. 3

IN-SITU ASSAY OF GLOVEBOXES AND VESSELS

In-situ assay of the residual plutonium content of gloveboxes and vessels prior to removal and size reduction is necessary to satisfy criticality safety requirements and to provide projectplanning information. Considerable experience has been gained in performing such measurements (more than 60 in-situ glovebox measurements have been taken) and has led to the development of a unique and versatile instrument system called DISPIM (Decommissioning In-Situ Plutonium Inventory Monitoring) specifically for such tasks.

The DISPIM system (Fig. 4) incorporates of a number of individual neutron counting modules which consist of two 3He detectors encased in a block of polyethylene (approximate dimensions 1200mm x 200mm x 110mm). The modules are deployed around the accessible faces of the glovebox on mobile stands which have been designed for maximum stability (in order to satisfy plant safety requirements) and easy dismantling and relocation. The system electronics and data recording facilities are housed in a remote sealed cubicle to prevent contamination of these components.

The configuration of the DISPIM system (i.e. the number of detector modules used and their relative positions) will vary from item to item depending on size and accessibility. Objects ranging in size from 200 litre drums to large process vessels (say 3m x 3m x 3m) can be assayed. Once the system is in position a standardisation check (using a small neutron source) is performed on all the detector modules to ensure their correct functioning before the measurement is conducted.

Fig. 4

The total Pu content of each glovebox is obtained by combining the results of a Neutron Coincidence Count (NCC) from the DISPIM system with Pu isotopic composition data which is either known or measured using a HRGS system and Pu isotopic composition algorithms. This measurement of the plutonium content is independent of the Pu isotopic and chemical composition.

The usual method of calibrating the DISPIM system is based upon "posting" a 252Cf source of known activity into the glovebox once all the detection modules are in position. If entry into the glovebox is not possible then the calibration can be performed either by reproducing the measurement geometry in free space or through the use of radiation transport modelling. Corrections which are required in order to account for the contribution to the observed neutron coincidence count from spontaneouslyfissioning material in neighbouring gloveboxes are also determined at this stage.

Calibrations based on the most likely locations of any residual Pu (obtained from information from the RADSCAN 600 system or from process knowledge or operator experience etc.) are used to determine the "most probable" Pu mass, whereas the "worst case" or criticality control Pu mass value is obtained by assuming the most pessimistic measurement conditions.

Measurement times for the DISPIM system are typically of the order of a few hours and total measurement errors of below 50% (or significantly less if the residual Pu locations are known) are usually achieved for Pu masses of approximately 10 - 20 grams.

SIZE REDUCTION AND DRUM PACKING

Once the individual gloveboxes have been shown to be belowcriticality safety limits, they are usually size reduced and packed into 200 litre drums. An alternative option is simply to load the gloveboxes directly into a box (or crate) for interim storage.

If size reduction is the chosen option, it is performed using a variety of cutting techniques within a specially constructed working area known as an RMC (removable modular containment). To ensure compliance with the nuclear safety requirements of drum filling, a "piece" monitor is used to assay the size reduced waste "pieces" before they are loaded into storage drums. The "piece" monitor (Fig. 5) is designed around an instrument bulge in the RMC and therefore remains outside the high contamination area. Each glovebox "piece" is placed in the instrument bulge by personnel within the RMC for assay of the fissile material. A running total is kept of the fissile mass of all the waste items consigned to each individual waste drum. The "piece" monitor automatically requests a new drum if the addition of a waste piece would raise the total fissile content of the drum currently being filled above the defined nuclear safety limit.

Fig. 5

As with the TRU-D and DISPIM systems, the "piece" monitor determines Pu masses through the combination of results from a NCC system and an HRGS system. If required, the gamma spectrum recorded by the HRGS system can also be used to determine the Pu : U ratio and U enrichment figure. Another optional feature of the system will warn of the presence of PuF4, a factor which can cause a significant increase in measurement errors. Once the presence of PuF4 has been identified, the measured Pu mass and its associated error value can be reassessed.

The "piece" monitor uses a short assay time (typically 5 minutes) in order to maximise the efficiency of the size reduction and drum packing operations. Total measurement errors of less than 15% are usually obtained for Pu masses of the order of a few grams. Several such "piece" monitors have already been supplied to Decommissioning Unit at Sellafield and they have been usedextensively in decommissioning operations.

ACCURATE DRUM ASSAY PRIOR TO INTERIM STORAGE

The total fissile mass values provided by the "piece" monitor satisfy nuclear safety requirements for the movement of drums of TRU waste. This allows the drums to be transported from the building in which they were generated, for a final accurate assay before interim storage. This final drum assay is performed by a mobile system whose purpose is to provide a highly sensitive, versatile, non destructive measurement for the characterisation of radioactive constituents in low level and transuranic waste. The system consists of an Imaging Passive Active Neutron Counter (IPAN) supplemented by high resolution Gamma Energy Analysis (GEA). Active mode neutron analysis uses a pulsed Zetatron source (108 neutrons/second) and the Differential Die Away (DDA) measurement technique to assay fissionable materials in the waste such as 235U and 239Pu. Passive mode neutron analysis determines the content of spontaneously fissioning isotopes such as 240Pu or 244Cm. For both active and passive neutron measurements, 3He detectors arrangedin a 4p configuration are used for neutron detection. Passive and active mode neutron imaging analysis identifies and corrects for inhomogeneities in the spatial location of fissioning constituents. Automatic correction for matrix composition and neutron multiplicity analysis augment assay accuracy.

A single 20% efficient high purity germanium detector is used for the GEA measurement to identify and quantify gamma emitting radionuclides and to determine Pu isotopic composition. This analysis is equipped with peak search and strip algorithms, a library of peak centroids and activities,

statistical precision analysis and corrections for the energy dependence of the detector efficiency.

Each assay is accompanied by advanced systematic error correcting algorithms, gamma-ray and neutron diagnostic packages and automatic data quality checking. IPAN/GEA systems are capable of performing assays in the range between milligrams and hundreds of grams of 235U or total Pu in 55 gallon or 85 gallon (overpack) drums. This range permits discrimination at 10 nCi/g for nearly all low level waste matrix categories and assures safeguards measurement requirements are met for drums with higher fissile contents. IPAN/GEA systems are operationally proven and comply with applicable waste disposal regulations. An easy-to-use operator interface is managed from a Microsoft Windows platform.

The measurement system is housed in a custom built 13' x 10' wide x 40' long reinforced semi trailer (Fig. 6) equipped with shock and vibration isolators. When outfitted with drum loading and conveyor apparatus, the total weight of the trailer is 35,000 lbs. An air conditioned control room houses measurement electronic modules and computers. This room is isolated from the measurement system section to reduce radiological exposure to operators.

Fig. 6

CONCLUSION

As a result of substantial operational experience a wide range of radiometric monitoring equipment is now available to support the decommissioning of redundant Pu facilities. All of the monitoring systems have a proven track record of exceptional performance in an industrial plant environment. The development of these instruments which has occurred as a result this operational experience has led to a capability to offer the use of these systems as a service as well as a product. The instrument systems are all transportable, robust, versatile and designed for easy decontamination. BIL and PSC personnel have gained extensive knowledge and experience in the operation of instrumentation in support of decommissioning operations. These factors combine to make the lease of instrument systems, supported by skilled technical personnel, a guaranteed high quality, low risk service, which will be very attractive for short-term decommissioning/waste retrieval operations.

G. Harris
Benchmark Environmental Corporation
Albuquerque, New Mexico 87110

ABSTRACT

In compliance with the Federal Facilities Compliance Agreement, Los Alamos National Laboratory (LANL) is striving to ship its low-level mixed waste (LLMW) off site for treatment and disposal. In order to ship LLMW

off site to a commercial facility, LANL must request exemption from the Department of Energy Order 5820.2A, Radioactive Waste Management, requirement that LLMW be shipped only to Department of Energy facilities. Because the process of obtaining the required information and approvals for a mixed waste shipment campaign can be very expensive, time consuming, and frustrating, a well-planned program is necessary to ensure that the elements for the exemption request package are completed successfully the first time. LANL is developing a program that is cost-effective, quality-driven, and compliance-based. This program, partially described in LANL's Low-Level Mixed Waste Off-Site Treatment and Disposal Management Plan (currently in draft form), encompasses selecting a qualified analytical laboratory, developing a quality project-specific sampling plan, properly sampling liquid and solid wastes, validating analytical data, documenting the waste characterization and decision processes, and maintaining quality records. The products of the program are containers of waste that meet the off-site facility's waste acceptance criteria, a quality exemption request package, documentation supporting waste characterization, and overall quality assurance for the process. Documentation of the decision process provides substantiation for containers of waste remaining on site, thus demonstrating a good faith effort to comply with the Federal Facilities Compliance Agreement and state agreements.

The program consists of elements that are common to all shipment campaigns, can be customized from templates, and are unique for each individual shipment. The majority of the effort is accomplished with the first off-site shipment. This program provides guidance for achieving a successful shipment campaign, is flexible to allow for customization to each waste stream, and can be revised based on lessons learned with each campaign.

The primary goal of the program is to provide an avenue for documenting decisions, procedures, and data pertinent to characterizing waste and preparing it for off-site treatment or disposal. Each shipment may require that certain elements of the program be revised, but the overall quality and consistency of each shipment will be assured. As LANL continues to develop this program, each LLMW shipment campaign provides new avenues for improvement.

INTRODUCTION

Until recently, treatment technologies and disposal capacities for low-level mixed waste (LLMW) generated at a Department of Energy (DOE) facility did not exist, requiring that all LLMW generated atLos Alamos National Laboratory (LANL) be placed in storage. Because of the recent developments in treatment technologies and disposal capacities, LLMW can now be shipped off site from LANL for treatment and disposal. Each off-site treatment, storage, and disposal facility (TSDF) has its own waste acceptance criteria (WAC) that must be met before the waste is shipped. To ship LLMW to any off-site TSDF, LANL must ensure that the waste meets these criteria. This requires obtaining accurate characterization information for the waste and certifying that the waste meets the waste management requirements of DOE Order 5820.2A, Radioactive Waste Management (1). To ship to a commercial facility, LANL must obtain an exemption from the DOE Order 5820.2A requirement that LLMW be shipped only to DOE facilities.

The most accurate characterization information for a waste stream is usually provided by sampling the waste and obtaining analytical data for

specified analytes. Sampling operations require strict compliance with quality assurance (QA) criteria to ensure the following: each collected sample is representative of the original waste stream, the analytical data provide a high level of confidence regarding the precision and accuracy of the waste stream constituents, and data quality objectives (DQOs) are met. The draft Low-Level Mixed Waste Off-Site Treatment and Disposal Management Plan (the Plan) being developed by LANL is quality-driven and compliance-based and provides procedures that ensure a quality program for sampling, characterizing, and shipping LLMW off site (2). The Plan encompasses selecting a qualified analytical laboratory; developing a quality project-specific sampling plan; properly sampling liquid and solid wastes; validating analytical data; and maintaining quality records. Implementation of the Plan provides documentation of decision processes, sampling strategies and procedures, deviations from established protocols, and data pertinent to the quality of the program. The goal of the Plan is to provide the waste certification official with a complete project package that demonstrates a quality program and manifests a high confidence level for the waste characterization data required to meet DOE requirements and the TSDF's WAC.

Although DOE Order 5820.2A is the regulatory driver for the exemption package documentation, this program focuses on establishing a process for obtaining and documenting accurate and complete waste characterization information, which is beneficial to all waste management activities. Therefore, even waste management activities not affected by DOE Order 5820.2A benefit from this program.

ELEMENTS OF THE PROGRAM

This program consists of the following elements:

- The DOE facility's waste management database
- A project database for the data being compiled
- A project-specific sampling plan
- A TSDF WAC checklist
- An analytical laboratory evaluation form
- An analytical data validation form
- A checklist based on DOE Order 5820.2A exemption request instructions
- The DOE exemption request package (ERP)

The majority of these elements can be developed at the outset of the program and used each time a shipment of waste is being prepared. For those elements that are shipment-specific, templates can be developed initially and customized to each shipment as it is being prepared.

Common Elements

The following elements of the program are common to all off-site shipments of LLMW and can be developed at the outset of the program.

- The waste management database
- A project database
- A checklist of the TSDF WAC
- An analytical laboratory evaluation form
- A form to document the validation of analytical data
- A checklist based on DOE Order 5820.2A exemption request instructions

The waste management database is the database used by the DOE facility to track its waste. To support this program, the database should have the ability to generate reports based on a key word search, the key word being the waste stream identifier or description. The generated report should provide container numbers and characterization information for the waste identified for off-site shipment.

The project database provides the quality record for the entire program, including the rationale for decisions made. Once this database has been formatted, data entry is all that is required for each off-site shipment of LLMW. This database can consist of fields for the following information:

Unique record number identifying the shipment (each shipment of waste constitutes its own database record)

Name, address, and telephone number of the TSDF to which the waste is being shipped

Waste stream identifier (the basis for the waste selected for shipment)

Project-specific sampling plan document number

Analytical laboratory selected

Container numbers, with access to the following subfields

- Rationale for eliminating containers
- Containers selected for sampling and analysis
- Analytical results

Characterization information for each container

Compliance of each container with TSDF WAC, with access to a subfield for any details or explanations

Comments pertaining to the program process

When identifying a TSDF available for the selected waste stream, it is important to obtain the most current WAC document applicable to the specified waste stream. The WAC is developed into a checklist, which is used to determine if each waste stream meets the WAC. Each checklist for different TSDFs can be formatted into the project database as a subroutine that is called up as applicable. Once the WAC checklists are developed, they are used for each shipment of waste to the specified TSDF. Revisions to the checklists are necessary only as the TSDF revises its WAC.

Selecting an analytical laboratory for sample analysis requires an evaluation of the available laboratories to determine which one is best suited for and capable of performing the necessary analyses. An evaluation form is developed using the criteria established in 10 CFR 830.120, "Quality Assurance Requirements," (3) the Environmental Protection Agency's (EPA's) Test Methods for Evaluating Solid Waste, Physical/Chemical Methods (SW-846) (4), and the Handbook for Analytical Quality Control in Radioanalytical Laboratories (5). The TSDF may also mandate its own requirements for the analytical laboratory, which must be taken into account when developing the evaluation criteria. These requirements can be developed as an attachment to the template created from the regulatory criteria.

To ensure that analytical data is of acceptable quality, it must be validated against established acceptance criteria. A data evaluation form is developed once for all analytical data. Specific sections of the form that do not apply to the data being validated can be marked "not applicable;" thereby eliminating the need to create new forms for each type of data. The criteria for data validation are based on the analytical method used, the analyte of interest, acceptable ranges for quality control (QC) sample results, and established DQOs. Specific validation criteria are obtained from EPA's SW-846.

Finally, to facilitate the preparation of a DOE ERP, a checklist based on DOE Order 5820.2A exemption request instructions is developed. This checklist can be developed by one DOE facility and shared with others. A selection of the elements of this checklist is provided below. Each

element is identified as being either common to all shipments (common), able to be customized from a template (template), or needing to be developed for each unique shipment (unique).

- Waste characterization program description (common)
- Waste certification program description (common)
- Waste moratorium implementation program description (common)
- Method(s) used to characterize the waste (template)
- Comparison of DOE Order 5820.2A requirements with the criteria used by the agencies regulating the TSDF (template)
- Options considered and cost estimates for these options, indicating that off-site treatment or disposal is optimal (template)
- Description of waste types (unique)
- Detailed waste characterization of the waste to be shipped (unique)

Template Elements

Templates can be developed for the following elements:

- Project-specific sampling plan
- Certain DOE ERP information

Developing a template involves generating an outline of the information required, providing the common information, and providing guidelines for developing the waste-specific information. Developing and using template information minimizes the need to recreate information common to all shipments of LLMW and to research requirements for information specific to each shipment, thereby facilitating the rapid staging of waste for shipment and optimizing cost effectiveness.

A project-specific sampling plan documents the specific sampling operations involved with obtaining representative samples from the selected waste containers for analysis. An outline for a sampling plan consists of the following elements:

- Sampling strategy and method used to ensure that the samples collected represent the originating waste stream
- Specific sampling protocol
- QA/QC requirements specific to sampling operations
- Health and safety concerns unique to each waste stream
- Roles and responsibilities of the personnel involved with the sampling operation
- Sample container and volume requirements
- Sample preservation methods
- Sample packaging requirements
- Sample shipping requirements, if applicable
- DQOs

Most of these elements can be taken from template information and customized to the specific sampling operation based on the waste stream. For example, sampling strategies and preservation techniques are provided in EPA's SW-846, generic sampling procedures can be developed to encompass most types of waste, and QA/QC requirements and DQOs should be consistent for all sampling operations. However, each of these elements, especially the sampling strategy, must be adapted to the characteristics of the waste being sampled. The sample container and volume requirements are based on the analytes of interest and the TSDF WAC; therefore, they need to be developed specifically for each sampling plan. Finally, although certain health and safety concerns are common to all sampling operations, specific concerns based on the characteristics of the waste being sampled must also be addressed.

Certain information required in a DOE ERP can be developed once and inserted into each ERP. For example, a description of the DOE facility's waste characterization program and waste certification program would change little over time. Therefore, these descriptions can be prepared at the outset of the first DOE ERP and copied into each one after that. The information describing the TSDF and its licenses, permits, and operating record can also be developed once and inserted into other DOE ERPs for waste being shipped to that particular TSDF.

PROCESS OF THE PROGRAM
